The Journal of
THE AMERICAN ECONOMIC ASSOCIATION

14-15

THE AMERICAN ECONOMIC ASSOCIATION

Founded in 1885

OFFICERS

President

EDWARD S. MASON, Harvard University

President-elect

GOTTFRIED HABERLER, Harvard University

Vice-Presidents

ALBERT G. HART, Columbia University

RICHARD A. MUSGRAVE, Princeton University

Secretary-Treasurer and Editor of Proceedings

HAROLD F. WILLIAMSON, Northwestern University

Managing Editor of the American Economic Review

BERNARD F. HALEY, Stanford University

EXECUTIVE COMMITTEE

Elected Members of the Executive Committee

J. KENNETH GALBRAITH, Harvard University

RALPH A. YOUNG, Board of Governors, Federal Reserve System

EWAN CLAGUE, U. S. Department of Labor

CHARLES P. KINDLEBERGER, Massachusetts Institute of Technology

ROBERT TRIFFIN, Yale University

W. ALLEN WALLIS, University of Chicago

Ex-Officio Members

THEODORE W. SCHULTZ, University of Chicago

PAUL A. SAMUELSON, Massachusetts Institute of Technology

Publication and business office at Curtis Reed Plaza, Menasha, Wisconsin.

THE AMERICAN ECONOMIC REVIEW, including four quarterly numbers, the *Proceedings* of the annual meetings, the *Directory* and supplements, is published by the American Economic Association and is sent to all members five times a year, in March, May, June, September and December.

Membership dues of the Association are \$6.00 a year, \$5.00 of each year's dues being in payment of a year's subscription. Subscriptions to the REVIEW by nonmembers are \$6.00 a year. Single copies, \$1.50.

Correspondence relating to the *Papers and Proceedings*, the *Directory*, advertising, permission to quote, business matters, subscriptions, membership and changes of address may be sent to the secretary, Harold F. Williamson, Northwestern University, Evanston, Illinois. To be effective, notice of change of address must reach the secretary by the 15th of the month previous to the month of publication.

Second-class postage paid at Menasha, Wisconsin. Printed in U.S.A.

PAPERS AND PROCEEDINGS

(In May 1962 Number)

BUSINESS BEHAVIOR, STUDIES IN

Investment Plans and Realizations	R. EISNER	190
Location Decisions of Manufacturers	E. MUELLER AND J. N. MORGAN	204
The Predictive Value of Surveys of Business In- tentions	A. M. OKUN	218
<i>Discussion</i> by D. H. BRILL		226

BUSINESS CYCLES, INTERNATIONAL TRANSMISSION OF: PROBLEMS AND POLICIES

The Postwar Business Cycle in Western Europe ..	M. Gilbert	93
Economic Instability in an International Setting ..	J. J. POLAK AND R. R. RHOMBERG	110
<i>Discussion</i> by W. S. SALANT, R. E. CAVES, E. DESPRES		119

CONSUMER SOVEREIGNTY, REAPPRAISAL OF THE DOCTRINE OF

The Costs of Automobile Model Changes Since 1949	F. M. FISHER, Z. GRILICHES, AND C. KAYSEN	259
On the Principle of Consumers' Sovereignty	T. SCITOVSKY	262
Consumers' Sovereignty Revisited, and the Hos- pitality of Freedom of Choice	J. ROTHENBERG	269
<i>Discussion</i> by A. BERGSON, S. WELLISZ, W. J. BAUMOL		284

ECONOMIC DEVELOPMENT, PROBLEMS OF

The Role of the Price Structure in Economic De- velopment	K. E. BOULDING AND P. SINGH	28
Laborsaving in Economic Growth	J. H. POWER	39
The Development of Entrepreneurship	G. F. PAPANEK	46
<i>Discussion</i> by E. E. HAGEN, A. M. KAMARCK, F. C. SHORTER		59

ECONOMISTS, THE MARKET FOR

The Supply of Economists	E. CLAGUE AND M. LEVINE ...	497
The Demand for Economists	F. M. BODDY	503
The Functioning of the Market for Economists ..	G. G. SOMERS	509
<i>Discussion</i> by S. E. HARRIS, H. D. MARSHALL, G. C. SMITH		519

FAMILIES, ECONOMIC BEHAVIOR OF

Microanalytic Models of the United States Econ- omy: Need and Development	G. H. ORCUTT	229
Toward a Microanalytic Model of the Household Sector	A. S. GOLDBERGER AND M. L. LEE	241
<i>Discussion</i> by R. SUMMERS, D. B. SUITS, M. E. DINGLE		252

INVITED LECTURE

New Developments in the Theory of the Firm ...	H. A. SIMON	1
<i>Discussion</i> by W. A. WALLIS, P. F. LAZARSFELD, J. LINTNER		16

THE LAGGING U.S. GROWTH RATE

How to Raise the High-Employment Growth Rate by One Percentage Point	E. F. DENISON	67
---	---------------------	----

Technical Progress, Capital Formation, and Economic Growth	R. M. SOLOW	76
Discussion by G. COLM, J. CORNWALL, A. SMITHIES		87
THE REPORT OF THE COMMISSION ON MONEY AND CREDIT		
An Essay in <i>Petitio Principii</i>	M. FRIEDMAN	291
The Report of the Commission on Money and Credit	W. L. SMITH	302
Report of the Commission on Money and Credit: A Commentary	R. A. YOUNG	311
Discussion by R. ROBINSON, R. LINDSAY		320
RESEARCH AND DEVELOPMENT, THE ECONOMICS OF		
Determinants of Inventive Activity	J. SCHMOOKLER AND O. BROWNLEE	165
Research and Development, New Products, and Productivity Change	W. E. GUSTAFSON	177
Discussion by Z. GRILICHES, J. W. MCKIE		186
SOVIET ECONOMIC PLANNING		
Input-Output Analysis and Soviet Planning	H. S. LEVINE	127
The Scale of Soviet Industrial Establishments	L. SMOLINSKI	138
On Patterns of Technological Choice in Soviet Industry	D. GRANICK	149
Discussion by L. G. REYNOLDS, J. BLACKMAN, A. ERLICH		158
TAX PROBLEMS		
Income, Consumption, and Property as Bases of Taxation	R. GOODE	327
Tax Incentives for Investment	E. C. BROWN	335
The Sensitivity of the Yield of Personal Income Tax in the United Kingdom	A. R. PREST	346
Discussion by G. F. BREAK, O. ECKSTEIN, M. I. WHITE		349
THE TEACHING OF ECONOMICS		
The Content of the Introductory Course	B. F. HALEY	474
Relation of the Undergraduate Major to Graduate Economics	R. RUGGLES	483
Discussion by R. BRANDIS, K. D. ROOSE, C. M. STEVENS		490
TRANSPORTATION IN ECONOMIC DEVELOPMENT, THE ROLE OF		
Air Transport and Economic Development: Some Comments on Foreign Aid Programs	H. HEYMANN, JR.	386
Planning for Transport Investment in the Development of Iran	H. J. KAUFMANN	396
Transportation and Technology	W. OWEN	405
Discussion by J. R. NELSON		414
TRANSPORTATION PROBLEMS IN THE AMERICAN ECONOMY		
Federal Transport Regulatory Policy	M. P. ARTH	416
The Pricing of Highway, Waterway, and Airway Facilities	J. C. NELSON	426
The Merger Movement in Transportation	K. T. HEALY	436
Discussion by M. J. ROBERTS, D. F. PEGRUM		445
URBAN REGIONS, SYSTEMS OF ECONOMIC ACCOUNTS AND ANALYSIS FOR		
A National System of Metropolitan Information and Analysis	H. S. PERLOFF	356

Design and Use of Regional Accounts	W. Z. HIRSCH	365
Organization for Data Collection, Analysis, and Reporting	H. COHEN	374
<i>Discussion</i> by M. B. GIVENS, F. T. MOORE		381
WATER RESOURCE USE, ECONOMICS OF		
The Political Economy of Water Development ...	V. OSTROM	450
Extensions of Benefit-Cost Analysis	G. S. TOLLEY AND C. HARRELL	459
<i>Discussion</i> by S. A. MARGLIN, J. W. MILLIMAN		469

CONTRIBUTORS:

Leading articles are marked (a); communications (c); papers read at the annual meeting, published in the Papers and Proceedings, separately paged, are marked (p); review articles (r); and all others are book reviews.

NUMBER ONE

ECONOMISTS AND THE HISTORY OF IDEAS*

By PAUL A. SAMUELSON

"For there are, in the present times, two opinions: not, as in former ages the true and the false; but the outside and the inside."

J. M. Keynes (1921)

"The proper study of Mankind is man." So said the infallible poet. And past experience at these annual gatherings of the sons and daughters of Adam Smith suggests that the popular subject of discussion among economists is not so much economics as economists. Usually the annual presidential address is an exception—an exception that does not always improve upon the rule.

According to our annals, an expiring president of this occult body begins with two choices. He may, on the one hand, give an address that summarizes his lifework or his basic contribution to some important field of scholarship. Thus, my old teacher, Paul H. Douglas, just as he was about to come out of his academic cocoon and emerge as a senatorial butterfly, gave his 1947 address on the Laws of Production, summarizing his decades of work measuring statistical production functions.

I am afraid this choice is not open to me. My own scholarship has covered a great variety of fields. And many of them involve questions like welfare economics and factor-price equalization; turnpike theorems and osculating envelopes; nonsubstitutability relations in Minkowski-Ricardo-Leontief-Metzler matrices of Mosak-Hicks type; or balanced-budget multipliers under conditions of balanced uncertainty in locally impacted topological spaces and molar equivalences. My friends warn me that such topics are suitable merely for captive audiences in search of a degree—and even then not after dark.

This leaves me still with several possible choices. For one thing, I can always talk about methodology. But although my children think of me as a remnant of "the olden days," to myself I seem just re-

* Presidential address delivered at the Seventy-Fourth Annual Meeting of the American Economic Association, New York, December 27, 1961.

cently to have become emeritus from the category of *enfant terrible*; and the only thing more terrible than the sight of an immature youth is the sight of a half-baked elder statesman. So, that part of methodology which consists of passing on good advice concerning the scholarly pitfalls to avoid and the proper paths to climb, I had better avoid.

But there is another possibility: I could give a sermon tonight on the use and misuse of mathematics in economics. This subject is the only commodity in the world that seems not subject to Gossen's law of diminishing marginal utility. It was only yesterday that three successive presidential addresses touched upon this delicious topic; and the strongest of those attacks on mathematics led to so resonant a response with this annual audience as to give rise to a standing ovation for the speaker.

Thomas Hardy remarked, "If the Archbishop of Canterbury says that God exists, that is all in the day's business; but if he says God does not exist, there you have something really significant." What a Daniel-come-to-Judgment I would be, if I, the lamb that strayed fustus' and mustus' from the fold, were to testify before God and this company that mathematics had all been a horrible mistake; that right along, it has all been there in Marshall, Books III and V; and that the most one needs for life as an economist is a strong voice, and a compass and ruler.

I wish I could be obliging. Yet even if my lips could be brought to utter the comforting words, like Galileo I would hear myself whispering inside, "But mathematics does indeed help."

I am left then finally with one choice. This evening I shall talk less about technical economics than about economists. Where do we members "of the most agreeable of the moral sciences" fit in the great stream of ideas and ideologies? On this solemn occasion I shall eschew gossip, leaving that to the corridors and lobbies. But I shall unavoidably have to deal with personalities and names if I am to explore the interrelations between professional economic thought and the general history of ideas.

I. *Within the Looking Glass*

As my old teacher Schumpeter used to say, "We are all girls here together." Hence, mine can be the view of an insider looking in, and an insider looking out.

I begin with two books. One is a work of scholarship; the other is, and you will excuse the distinction, merely a textbook. Compare *The History of Economic Analysis* by Joseph Schumpeter with *The History of Economic Doctrines* of Gide and Rist, which students used to study in my day when preparing for general examinations. I dare say that

all the names mentioned by the latter authors can be found in Schumpeter's index. But how different is the emphasis: reading Gide and Rist you would be forgiven for thinking that Robert Owen was almost as important as Robert Malthus; that Fourier and Saint-Simon were much more important than Walras and Pareto. The A. Young in their index is, of course, Arthur Young, not Allyn Young.

Now turn to Schumpeter. Everything is there; no name left out. But now it is Marshall, Walras, Wicksell and such people who steal the stage. Of course Adam Smith is given his due. But what a due! He is rather patronizingly dismissed as a synthesizer who happened to write the right book at the right time: his analytic contributions are certainly minimized.

How can we account for these differences? By the fact that Schumpeter is writing some 40 years after Gide and Rist? Only in the smallest part, I think. By 1913 Wicksell, Wicksteed, and Wieser had done their great work, but only Wieser gets a mention from Gide and Rist—one mention. The treatment of Walras is even more indicative. Walras is indeed mentioned by them; but yet not primarily for his work as a theorist so much as for his views on nationalization of land, free trade, and the State—views which Pareto and Schumpeter thought of as simply silly, like Irving Fisher's food fads and teetotalism. To verify that I am not having sport by picking on a particular set of authors, turn from Gide and Rist to Alexander Gray's brief book, the busy student's friend, to see how Walras fares there. In Gray, Leon Walras is "crowded out" by his father Auguste and is referred to as the "younger Walras," which is a little like referring to Maynard Keynes as the "younger Keynes."

No one can really deny that we have two different sets of standards here. When I began graduate study at Harvard in 1935, Schumpeter rather shocked me by saying in a lecture that of the four greatest economists in the world, three were French. (I had thought the non-Frenchman was English, probably Adam Smith; but after looking into Schumpeter's later book for the purpose of checking, I think my inference must have been incorrect and that he then meant Alfred Marshall rather than Smith.) And who were the Frenchmen?

Of course, one was Leon Walras, whom Schumpeter had no hesitation in calling the greatest economist of all time, by virtue of his first formulation of general equilibrium. Today there can be little doubt that most of the literary and mathematical economic theory appearing in our professional journals is more an offspring of Walras than of anyone else (and I stress the adjective *literary*). The comparison that Lagrange made of Newton is worth repeating in this connection: Assuredly Newton was the greatest man of science, but also the luckiest.

For there is but one system of the world and Newton was the one who found it. Similarly, there is but one grand concept of general equilibrium and it was Walras who had the insight (and luck) to find it.

I ought to add that this rating by Schumpeter deserves more credit, coming in 1935, than it would coming today. For it had predictive value as to what was to happen to our professional writings. Back in 1935, Marshall was still propped up on his throne and in large parts of the world even the zealots of the mathematical method tended to look upon Walras merely as the predecessor of the great Pareto. The bourse for professional reputations shows changing price fluctuations: if at one time Alfred Marshall was overpraised and quoted at an inflated price which left little of consumer's surplus to the buyer, he had to pay for this by later being sold at an overdiscount—as will become evident.

Since I ought not to leave you waiting for the other shoes to drop, I hasten to name the other Frenchmen. One is Cournot, a choice that will not seem too surprising. Certainly there is a professional competence about the 1838 Cournot, in the field of partial equilibrium, monopoly and oligopoly, that the modern literature only reattained by 1930. (Think only of the *rediscovery* in *this* century of the concept of marginal revenue!) I do not know that the name of Schumpeter's final giant will seem so obvious a choice. It is François Quesnay, who is deemed to be great on account of his cryptic *Tableau* and anticipation of the circular flow of economic life. Back in the days before Leontief and the resurrection of Karl Marx's Volume 2 model of circular reproduction, I thought this last choice even more far-fetched than I do today.

II. *The Pecking-Order of Analysts*

I need not labor the point farther. Within economics, we economists rate writers of the past in a quite different order than does the outside world. And, as far as economic analysis itself is concerned, the present generation of economists gives a quite different ranking than did earlier generations of economists.¹

Now I am not really concerned here with the history of pure theory and the changing fortunes of different writers. A critic can rightly argue that Gide and Rist were writing a history of economic *doctrines*, while Schumpeter was writing a history of economic *analysis*; and hence I ought not to be surprised if there turns out to be a considerable difference in emphasis. Who would want to deny that Cournot,

¹ There is a great deal of evidence that this is more than the view of the *avant garde* and more than a passing fad. One straw in the wind would be to examine the successive revisions since 1939 of a book that did not begin with any prejudice in favor of economic analytics, Eric Roll, *A History of Economic Thought*, 3d ed., Englewood Cliffs, N.J., 1956.

writing in 1838, had an analytical power and freshness that is breathtaking? But who in his right mind could argue that Cournot had been a great force on the history of ideas: what Paris *salon* preoccupied itself with sellers of mineral water? Except through possible indirect influences of his teachings, Cournot's impact on ideology must surely have been negligible.

I quite agree. In many ways the history of a subject's technical analysis is easier to write precisely because it need not involve the determination of social influencings.² Tonight we do not want to linger on analytics, except perhaps to draw the obvious moral that, if economists spend more and more of their time on highly technical mathematics and statistics, they must not be surprised if the intelligent man of affairs comes to ignore this part of their activities. It is true that Voltaire and Madame du Châtelet, his great and good friend, wrote profusely on Newton's universal law of gravitation; but this really amounted to vulgarization of that subject, gross vulgarization on the part of Voltaire and neat vulgarization on the part of that gifted lady. While we should not minimize the importance of vulgarization—I mean communication—we must not blink the fact that this is an area where Gresham's Law operates in its most remorseless fashion: vulgar vulgarization drives out subtle, just as strong ideology outsells weak.

The split, between "the inside look" of a subject in terms of the logic and experience of its professional development and its implications for the man-in-the-street or the academician down the campus, is well recognized. No one gets a Nobel Prize for an essay on the relationship of quantum mechanics to free will and God; but one who has already received such a prize will get a better hearing for his random or systematic thoughts on the topic. Nor, these days, do you get appointed to chairs of economics by virtue of your social elo-

² If the history of science is still generally in a crude form, that is primarily because scholars have just recently begun to take it seriously. In the case of mathematics, there is a most ludicrous ignorance of the true sequence of contributions: if a formula, such as Lagrange's interpolation formula, is attributed by name to a person, the betting is good that small research will show it appeared in earlier writings. What I have in mind here is not the statement that there is nothing new under the sun and all knowledge is a repetition of previously known knowledge: on the contrary, such a statement is the reverse of the truth; mathematical knowledge has been cumulative and, with enough research and luck, we might hope to clean up the false history of the subject. The situation in mathematics is especially simple if one takes the view that the objects of mathematical research are theorems and that most importance attaches to the date of their first rigorous *proof*. Thus, it is meaningful to say that the "strong ergodic theorem" goes back to G. D. Birkhoff in 1931, and that J. v. Neumann deserves the credit for two-person zero-sum game theory. (But if one is also interested in conjecture, heuristics and partial insight, the matter is not so simple. Some modern mathematicians, one feels, will rename Fermat's Last Theorem to Schwartz's Theorem if the first man to prove it happens to be named Schwartz.) In economics, datings are harder: thus I cannot tell you who first disproved "the labor theory of value," much less who originated it.

quence; indeed, until academic tenure has come, you are best advised not to write for *Harpers* or the *Manchester Guardian* (to say nothing of the *National Review* or the *New Republic*) lest you be indicted for superficiality.

Good writing itself can be suspect. (I interject that if good literary style is indeed a sin, it is not a sin that is very widespread among our economics brotherhood.) John Stuart Mill tells us in his remarkable autobiography that his father, James Mill, thought poetry was overrated; but that since poetry *was* overrated, young John ought to try his hand at it. I believe it was Yale's Tjalling Koopmans, himself a creative economist blessed with clarity of style, who advanced the austere argument that exceptionally fine writing is a biasing factor which might bring to an argument more attention and credence than it really deserved. There is something to this: but no one should be taken in by the false corollary that the *intrinsic* worth of an argument is enhanced by virtue of its being phrased obscurely. Having said this, one must add grudgingly that, while obscurity may not add to the intrinsic worth of an argument, it has often been a contributory ingredient to fame. How many Marxians have read *Das Kapital*—I mean read it through? Bernard Shaw once claimed that he was the only man in England, including H. M. Hyndman and contemporary Marxian leaders, who had read the book. Shaw himself was observed at the British Museum by Harcourt³ in the act of reading Marx (in the French translation, of course); so at least part of Shaw's claim may be true. But Shaw was sitting in the British Museum with a copy of *Capital* stretched before him and beside it a copy of the score of *Lohengrin*; one can guess on which he could have earned the higher exam grade.

This brings me to mention one of our members who is far away to-night toiling on a distant shore. I refer of course to J. Kenneth Galbraith and have in mind *The Affluent Society*. To compare this book with *The Theory of the Leisure Class* would be in some of our common rooms, to damn it; in some, to praise it. Gibbon tells us how he found his *Decline and Fall* on every boudoir table soon after its publication. When we economists think how often in recent years people have been asking us, "What do you think of *The Affluent Society*?"—and how embarrassing the question has been to so many of us busy beavers—we can appreciate that this work stands as good a chance as any of being read and remembered twenty years from now.

Yet always members of a guild have their defenses against the man who ventures away from home. "It was all in Keynes's 1930 *Saturday*

³ This gives Sir William Harcourt a second claim to fame, beyond that of his famous one-tenth truth: "We are all socialists now."

article, 'Economic Possibilities for Our Grandchildren.' " The title of the title came from Tawney's *The Acquisitive Society*. " About the need to spend more these days on public rather than private wants was already made eloquently by Alvin Hansen and in any case it involves a value judgment not a scientific finding. " Harvard professors may have incomes high enough to satiate them, but most people do not. " So what's the matter with big automobiles? Didn't you ever hear of Freud? And how about Jeremy Bentham's dictum concerning the equality of pleasures, 'Pushpin is as good as poetry?' " "Are commercially created wants different, or less satisfying, or less worthy than natural wants, whatever those may be?" "The book's style is superficially attractive but its message is not profound."

I am afraid people in the boudoir, today or twenty years from now, will not seek the benefit of our professional reactions. Within the body of economics itself, *The Affluent Society* will find a place that is proportionate to the new predictions about economic regularities it may suggest. But whatever the later verdict about the operational meaning of its propositions, we can no more recall it or wipe out half a line of it than we can—by professional exegesis—expunge Henry George's *Progress and Poverty* from the historical record.

III. Political Economists: Ourselves to Know

Leaving aside how our own profession rates and ranks the craftsmen of its trade, I now want to close in on the differences between our view of ideologies and *Weltanschauungen* and that of the intelligent man of affairs. Who do we think were the great *political* economists as against just great economists?

Adam Smith. Going back no earlier than Adam Smith, we can let Smith stand for the classical tradition. And, in my telescope, he stands on a pinnacle. While I think Smith is underrated as an economic theorist, it must be admitted that his impact as a political economist does not rest upon his having improved upon theories of his friend David Hume; nor upon his having anticipated the various refinements of Malthus, West, Ricardo, Torrens, and John Stuart Mill.

Here is a case where the inside view and the outside view are one. The intelligent man of affairs, and even Macaulay's schoolboy, were profoundly influenced by Smith's attacks on mercantilism and state interference and by his spirited championing of *laissez faire*. To be sure, the amateur never appreciates the nuances of Smith's position: e.g., his skepticism about the businessman's passion for tough competition; his definite role for limited government; his general pragmatism rather than dogmatism.

Still, it is significant that the great critics of the classical economists generally chose to controvert the *Wealth of Nations* rather than the writings of later members of his school.

David Ricardo. In time Ricardo came to be the whipping boy of the continental romantics and historicists. Yet there is not much evidence that they had to read him closely in order to find fault with his abstract methodology. I must confess that I find Ricardo hard to give semester-type grades to. He is par excellence an economist's economist. A sweet man, Ricardo is certainly one of the luckiest that ever lived. And here I have not so much in mind his success in speculating, although he was no slouch in that department, as some facts from his biography illustrate.⁴

Ricardo was lucky in being on the spot when the Napoleonic Wars were causing the value of money to misbehave in the most interesting fashion. He was lucky to have James Mill as taskmaster and press agent. He was lucky in having been deprived of higher education, so that his resulting written expositions had the clumsiness necessary to give that ingredient of obscurity so conducive to a reputation for great profundity. Finally, and I hope it comes as no anticlimax, Ricardo was lucky in being profound.

⁴Cut off for marrying outside his faith with a few thousand dollars, within twenty years Ricardo had become a millionaire a few times over, the equivalent in this present day of taxes, higher prices and higher general real incomes, to tens of millions of dollars. The Duke of Wellington may have regarded the battle of Waterloo as "a damned near close-run thing," but David Ricardo urged before the battle that his friend Robert Malthus go the limit in holding British government bonds; and Malthus, a parson with small means and a convex-from-above utility function, lived to reproach himself for not having followed that advice. Retiring young from business to devote himself to leisure, study, politics, and being a gentleman, Ricardo astutely realized that his numerous children were not chips off the old block in financial acumen; so, and this is purely my conjecture, being convinced by his studies that land rent tends to rise as capital and labor progressively grow, Ricardo arranged to buy self-sufficient gentry estates for his offspring, succeeding so well in his purpose as to keep his descendants out of shirtsleeves until the end of the century and, at the same time, conferring upon them the bonus of being absorbed into county society. At the urging of his friends, Ricardo indulged in conspicuous consumption by buying his way into Parliament. (He did this by invoking the later doctrine of "opportunity cost": i.e., he lent £20,000 interest-free to an Irish holder of a rotten borough, one which Ricardo never bothered to visit.)

Ricardo's parliamentary career was something of an anticlimax. He was not a gripping speaker, and the build-up of his reputation was a grave handicap. It is interesting that Ricardo was a genuinely disinterested man and generally favored measures that were against the interest of landlords. When once accused of having a special interest in some proposal, he candidly replied that his interests were so diverse that he himself could not tell on which side the balance of his Hicksian income effects would fall, thus showing himself to be a master of *quadratic* programming of the type needed for optimal Markowitz portfolio balancing; and little wonder, since in 1817 Ricardo's comparative cost theory had involved him in linear programming. One feels he was a natural at trading in, and arbitrating, Lagrangean multipliers and other dual-price variables. See Volume 10 of the Sraffa edition of Ricardo's work for most of the facts from which this account has been fabricated.

Once I had heard George J. Stigler say that Malthus was the best of economists, I heard myself replying: "That's funny. David Ricardo is the most overrated of economists." Probably this conversation tells more about Stigler and me than about Ricardo or Malthus. What I had in mind was this: Ricardo was a keen reasoner and almost always comes out to be logical in the end, if you follow his implicit and explicit definitions and assumptions. But he does not necessarily rough weather of the matters he deals with, and the reader is inclined to think him miraculous for being able to get to the bottom of the holes he has dug for himself by his mode of attack and exposition. Analytically, his theory of rent is excellent but not clearly better than or earlier than the contemporaneous theories of rent of Sir Edward West and Malthus. Ricardo did have a rigorously handled general equilibrium model of primitive type; but its dynamics merely elaborate on what is already in the population theory of Malthus and Smith, and ought not today to be regarded as very "magnificent."

His greatest tour de force was the theory of comparative advantage; and though it would be simply irrelevant to point out that Isaac Ger-vaise had developed similar notions in the preceding century, one has to take into account that Colonel Torrens, a mere mortal, had also developed pretty much the same analysis at pretty much the same time. Moreover, in most of the debates that Ricardo's work gave rise to, the points of his critics were well taken, not so much in proving that Ricardo's reasoning was wrong in terms of its assumptions, as in pointing out that his conclusions were apt to be misunderstood and were of limited significance. Instead of regarding it as a scandal that so much ink has had to be split over Ricardo's flirtations and retreats from a labor theory of value, his admirers think this makes him a seminal thinker.⁵ In short, the notion of Keynes that "Ricardo's mind was the greatest that ever addressed itself to economics" does not agree with my assessment of his high I.Q. or creativeness in relation to that of other economists.

Ricardo's name was certainly used as a rallying cry for the school that favored freer trade in England. But Smith had already made the needed points; if exaggeration is what was needed, Herbert Spencers and Bastiats can usually be found who are unencumbered by the subtleties of refined economic analysis. Moreover, detailed researchers will more and more reveal that the Ricardian School provided the background for early Victorian thinking but did not, in a detailed fashion

⁵ See my two papers on Ricardian systems, which elaborate on my views and give a physiocratic interpretation, "A Modern Treatment of the Ricardian Economy," *Quart. Jour. Econ.*, I, Feb. 1959, 73, 1-35; II, May 1959, 73, 217-31; also my paper on related Marxian models, "Wages and Interest: A Modern Dissection of Marxian Economic Models," *Am. Econ. Rev.*, Dec. 1957, 47, 884-912.

satisfactory to the historian of direct political development. Important influences upon such legislative events as the repealing of the Corn Laws. Indeed, Ricardo was subtle enough to muck up the un- minded case for harmonious free trade.

Jeremy Bentham, a friend of James Mill and Ricardo, was a character who would have been unbelievable if he had appeared in the nineteenth century. (He once seriously asked James Mill for his eldest son. James refused, that an excessive demand on friendship, but did lease him John to clean out the Augean stables of Bentham manuscripts; this was one of the feats of Hercules that John accomplished with distinction and at incredibly early ages.)

Bentham's influence on modern law and institutions has always been recognized by historians as having been great: the nineteenth century where legislation is concerned is truly Bentham's shadow writ large, as Dicey has said. Crane Brinton once quipped: "The New Deal had a good deal of old Bentham in it."⁶ And I have dared to suggest that the logic of Bentham's position would in later times have gone beyond his fortuitous individualism, so that his thought is really congenial to that of Fabians like Sidney Webb. Bentham, though not an economist's economist nor even primarily an economist, had I am sure an influence far greater than that of Ricardo.

Have I now not proved too much? Why then has Ricardo had the good press with posterity if my strictures are at all near the mark? I think the answer depends upon a different kind of luck. David Ricardo happens to be the darling both of the liberal economists who followed in his direct line and of the Marxian critics of capitalism. Like me, you may not agree with Ricardo's famous letter to Trower which says, "Political economy . . . should rather be called an enquiry into the laws which determine the division of the produce of industry amongst the classes who concur in its formation." But you can perceive how Ricardo's laconic and unsparing remarks about distribution would stimulate the so-called Ricardian socialists who regarded property incomes as exploitation of labor. And once Karl Marx took him up as an object of worthy study, Ricardo was, so to speak, in on both sides of the street. Having Piero Sraffa as an editor merely capped Ricardo's good luck.

John Stuart Mill. I pass by Nassau Senior and the other classical writers to mention Mill briefly. Mill was modest; Marshall was not. The world takes people too much at their word. The result is that Marshall's claims to analytical originality are received too seriously;

⁶ C. C. Brinton, *Ideas of Men: The Story of Western Thought*, London 1951, p. 392. Incidentally, Brinton's index has between Rhodes, Cecil and Richards, I. A. no Ricardo, David.

and Mill's forging of the general-equilibrium concept of demand and supply schedules, even before the 1838 date of Cournot's definitive partial-equilibrium formulation, is ignored by all but the true gourmets of economic theory, who recognize it as an analytical contribution of the first magnitude.

John Stuart Mill, son of a dogmatic father, was himself eclectic and had an engaging ability to change his mind when new facts or arguments became available or merely from rethinking old attitudes.⁷ It is almost fatal to be flexible, eclectic, and prolific if you want your name to go down in the history books: get known for one idea, however farfetched it may be—such as that the rate of interest has to be zero in the stationary state or that land is the source of all value—and you are sure to get at least a paragraph in the history books for it. Also, Mill had what Nietzsche once referred to as an offensively clear style.

Yet so great was Mill as a thinker and reflector that he was able to overcome these handicaps. His views on liberty will, even in the post-Freud world, never go out of date and can perhaps be summarized in the words of Mrs. Pat Campbell, Bernard Shaw's pen-mistress: People should be allowed to do anything they like—provided only they don't scare the horses in the street.

Mill is truly a transitional figure. Shaw shows this in one of his wittiest plays, *You Never Can Tell*. A typical Shavian New Woman returns from the West Indies after an absence of some 20 years to find that all her revolutionary Millian notions have become old-hat, superseded by new Fabian notions. The same conflict between the eighteenth and twentieth century went on in Mill's own mind: it was fa-

⁷Sweden's Gustav Cassel, whom the public regarded as about the world's leading economist in the 1920's and who might have become a truly outstanding scholar if his temperament had been different, is shown by the following story to be a good opposite to Mill. H. C. Sonne, the distinguished merchant banker and chairman of the National Planning Association, has told how Cassel visited at Sonne's family home in Denmark in the days around the First World War. A guest happened to mention that some scholar had just made a fresh study of the relationship between the price level and gold supply and had come up with conclusions strongly at variance with the famous Cassel thesis. When asked what he intended to do about it, Cassel replied as follows. "I have a son-in-law whom I have put through Divinity School at some considerable expense. Now that he has graduated and qualified for his diploma, he comes to me and says that he has lost his faith and asks what to do. My advice to him was simple: 'Just carry on as if nothing had happened'."

Relevant too is a conversation I had last month in London after I had given the Stamp Memorial Lecture in the University of London for 1961. In that lecture I discussed, among other things, some of the problems of economic forecasting and stressed the need for scientific validation and the desirability of each forecaster's going back ruthlessly to review *ex post* his *ex ante* predictions. "A great mistake," I was told by one of the best forecasters in English academic life. "It is fatal ever to read what you have earlier written. It breaks your nerve as a forecaster." His lips were smiling but his eyes looked serious.

ther James against friend Harriet with John advancing two steps and going back one. It is ironical that evolutionary socialism in England and elsewhere finds itself today backing up from its post-Benthamite insistence on nationalization of the means of production to something like the society dimly envisaged by Mill. No wonder Karl Marx hated Mill and denounced him as a vulgar bourgeois economist. Marx could recognize the enemy when he saw him. (Curiously, the well-read Mill either never heard of Marx or never thought him worth mentioning—this despite Mill's interest in the Revolution of 1848, the *Communist Manifesto* by Marx and Engels of that date, and Mill's survival beyond the 1867 date of *Capital* Vol. 1.)⁸

Karl Marx. From the viewpoint of pure economic theory, Karl Marx can be regarded as a minor post-Ricardian. Unknowingly I once delighted a southern university audience: my description of Marx as a not uninteresting precursor (in Volume 2 of *Capital*) of Leontief's input-output analysis of circular interdependence apparently had infuriated the local village Marxist. Also, a case can be made out that Marx independently developed certain vague apprehensions of underconsumptionist arguments like those of the *General Theory*; but on my report card no one earns too high a grade for such a performance, since almost everyone who is born into this world alive experiences at some time vague intimations that there is a hole somewhere in the circular flow of purchasing power and production. This seems to come on the same chromosome as the gene that makes people believe in Say's Law; and Marx's bitter criticisms of Rodbertus for being an underconsumptionist shows us that he is no exception.

As long as I am being big about admitting small merits in Marx, I might mention a couple of technical suggestions he made about business cycles that are not without some interest: Marx did formulate a vague notion of 10-year replacement cycles in textile equipment as the determinant of cyclical periodicity—which is an anticipation of various modern "echo" theories. He also somewhere mentioned the possibility of some kind of harmonic analysis of economic cycles by mathematics, which with much charity can be construed as pointing toward modern periodogram analysis and Yule-Frisch stochastic dynamics. A much more important insight involved the tying up of technological change and capital accumulation with business cycles, which pointed ahead to the work of Tugan-Baranowsky (himself a Marxian), Spiethoff, Schumpeter, Robertson, Cassel, Wicksell, and Hansen.

What can be gold in the field of fluctuations can be dirt in the context of pure economic theory. Marx claimed in Volume 1 that there was some interesting economics involved in a labor theory of value,

⁸ Cf. A. L. Harris, *Economics and Social Reforms*, New York 1958.

and some believe his greatest fame in pure economics lies in his attempted analysis of "surplus value." Although he promised to clear up the contradiction between "price" and "value" in later volumes, neither he nor Engels ever made good this claim. On this topic the good-humored and fair criticisms of Wicksteed and Böhm-Bawerk have never been successfully rebutted: the contradictions and muddles in Marx's mind must not be confused with the contradictions and mud-dles in the real world.

Marx, like any man of keen intellect, liked a good problem; but he did not labor over a labor theory of value in order to give us moderns scope to use matrix theory on the "transformation" problem. He wanted to have a theory of exploitation, and a basis for his prediction that capitalism would in some sense impoverish the workers and pave the way for revolution into a new stage of society. As the optimism of the American economist Henry Carey shows, a labor theory of value when combined with technological change is, on all but the most extreme assumptions, going to lead to a great increase in real wages and standards of living. So the element of exploitation had to be worked hard. Here Marx might have emphasized the monopoly elements of distribution: how wicked capitalists, possessed of the nonlabor tools *that are essential* to high production, allegedly gang up on the workers and make them work for a minimum. Or, were it not for his amazing hatred toward Malthus and his theory of population, Marx might have kept wages dismal by virtue of biological conditions of labor supply. The monopoly explanation he did not use, perhaps because he wanted to let capitalism choose its own weapons and assume ruthless competition, and still be able to show it up. Marx tried to demonstrate the same dramatic minimum character of real wages by means of his concept of the "reserve army of the unemployed."

Here is the real Achilles' heel of the Marxian theory of distribution and its implied prophecies of immiserization of the working classes. Under perfect competition, technical change will raise real wages unless the changes are so labor-saving as to raise the rate of maintainable profit immensely; Joan Robinson and others have pointed out how contradictory is Marx's notion that both profit rates and real wages can fall once Marx jettisons Ricardo's emphasis on the scarcity of land and the law of diminishing returns. Marx simply has no *statical* theory of the reserve army. If an appeal is made to a vague dynamic theory of technological displacement or recruitment from the country, close analysis will suggest that Marx (like Mill) was a very bad econometrician of his times, not realizing how much real wages in Western Europe had been raised by new techniques and equipment; and he was a bad theorist because his kind of model would almost certainly lead

to shifts in schedules that would raise labor's wages tremendously, in a way more consistent with the 1848 *Communist Manifesto's* paeans of praise for the capitalistic system than with his elaborated writings.⁹

In brief, technical change was gold in giving Marx cyclical insights, and dirt in giving him secular insights or an understanding of evolving equilibrium states. I should warn you that this is my opinion, and that I have always been surprised that I should be a virtual monopolist with respect to this vital analysis.

So far I have been talking about Marx as an economist. And I have been doing my best, subject to truth, to find some merit in him. (You may recall Emerson's neighbor in Concord: when he died the minister tried to find something to say at the funeral eulogy and ended up with, "Well, he was good at laying fires.") Even this represents a resurrection of Marx's reputation. Keynes, for example, was much more typical of our professional attitudes toward Marxism when he dismissed it all as "turbid" nonsense. (In view of the tendency of the radical right—for whom all Chinese look alike—to equate Keynesianism with Marxism, this ironical fact is worth nothing; and also its converse, since there is nothing communists deplore more than the notion that capitalism can be kept breathing healthily by the Keynesian palliatives of fiscal and monetary policy.)

Technical economics has little to do with Karl Marx's important role in the history of human thought. It is true that he and his followers felt that their brand of socialism differed from the sentimental brands of the past in that Marxist socialism was scientifically based and, therefore, had about it an inevitability and a special correctness. I need not labor the point before this group that the "science" involved was not that body of information about commercial and productive activity and those methods of analyzing the behavior relations which we would call economics. Political economy in our sense of the word was the mere cap of Karl Marx's iceberg. *Marx's bold economic or materialistic theory of history, his political theories of the class struggle, his transmutations of Hegelian philosophy* have an importance for the historian of "ideas" that far transcends his façade of economics.

Finally, one must never make the fatal mistake in the history of ideas of requiring of a notion that it be "true." For that discipline, the slogan must be, "The customer is always right." Its objects are what men have *believed*; and if truth has been left out, so much the

⁹ If migration from the country kept wages down to a city minimum, then the average wage and living standard of country-cum-city would be raised in accordance with the optimization desired by a technocrat—unless, again, Malthusianism is admitted back into the rural hovel.

worse for truth, except for the curiously-undifficult task of explaining why truth does not sell more successfully than anything else. Marx has certainly had more customers than any other one aspiring economist. A billion people think his ideas are important; and for the historian of thought that fact makes them important, in the same way that he would have to regard as diminished in importance the subject of Christianity, were it conceivable that it had been the religion merely of a transitory small group who once occupied the present country of Jordan or the state of New Mexico.

Alfred Marshall. What killed Mill for economists was not the socialism that killed it for Shaw's no-longer-New Woman. The marginalist school of Jevons-Walras-Menger perpetrated the murder. The roster of neoclassical economists would include the names of Böhm-Bawerk from Austria, J. B. Clark from the United States, Pareto from Italy, Wicksteed from England, and Wicksell from Sweden. But, for all that I have said earlier about his overvaluation in the market for reputations, few will doubt that Alfred Marshall of Cambridge is the prototype as *political economist* for this group. Marshall may now be old hat, but in his day he was some headpiece.

Marshall had strong social sympathies. At the same time he realized the harms that precipitate reform may bring. He was the prophet of moderation. If you graft Keynesian models of income determination on his thought and update his Victorianisms, you come close to the median member of this Association. His pupils filled, Foxwell could say by 1888, half the chairs of political economy in the United Kingdom; his influence permeated the other half and, methodologically speaking, today we are all Marshallians in the same sense that we are all higher primates.

But what has been Marshall's role in the history of ideas, the panorama of human thought? Never has he had one-hundredth the notice of, say, Henry George. I remember talking to the aged Frank Taussig at a Harvard Society of Fellows dinner before the war. Taussig quoted in despair a recent remark of John Dewey that Henry George was the greatest economist America had ever produced. George was the whipping boy for the economists just before my time; but within my time as a high school student in the Middle West, you could still find vestigial single-taxers, the old principal of my high school being one and my civics teacher another. George was not original in attacking incomes that come from land; as Foxwell said long ago, nationalizers of land we have always with us. This is understandable from the Hume-Ricardo recognition of rent as a price-determined (rather than price-determining) surplus to a factor in inelastic supply; but, as I have recorded elsewhere, my implicit belief that George gave a good

statement of Ricardian rent theory will not stand up after a search through *Progress and Poverty* for suitable quotations to put in an anthology. While the single-tax movement is recognizable today as being adverse to socialism, Henry George's attack on the inequality of property ownership in land was influential in turning many people toward socialism: thus Shaw tells us he became a socialist after hearing Henry George speak in London.¹⁰

Let us leave aside impact on the *hoi polloi*. What was Marshall's influence over his long life on the educated man of affairs? For years I looked for every trace I could find in books to show that someone other than a professional economist or student had read Marshall. I realize Marshall himself thought he was writing for the businessman; but anyone who looks at the *Principles* will realize that no businessmen in good Queen Victoria's time or since would be likely to find it attractive. (Actually Marshall's literary style is excellent, his graphs are in footnotes, and his rather awkward mathematics is buried in special notes at the end; but all this was to no avail.) I was able to come up essentially with only two bits of evidence, one negative and one positive. Pollock in his letters to Justice Holmes urged him to read Marshall; Holmes, who was a man of the most catholic interests, replied that he had tried it and it was not the dish for him. On the positive side, C.C.N.Y.'s great philosopher, Morris Cohen, reported somewhere that his inclination to be an eclectic in philosophy had received inspiration from Alfred Marshall's eclecticism in economics.

To be sure, Marshall taught at a leading world institution where half the English upper classes received their instruction. But actually he taught at Cambridge little more than 20 years, not very much longer say, than, I have taught at M.I.T. Sixty was a generous number for those who attended his popular lectures, and that was the beginning attendance not the final. As I know from personal conversations with Alfred North Whitehead, Marshall's contemporaries at Cambridge did not like him as a man ("He was a popish man who treated Mary Marshall very badly." "A second class mind?"); and one gets

¹⁰ Later Shaw went successively from Marxism to Jevonsism with a Fabian twist. Philip Wicksteed's conversion of Shaw away from Marxism is one of the most amusing and incredible incidents in the history of thought: for once a rational argument changed, or seemed to change, someone's mind.

It must have been on that same trip to England that Henry George debated Alfred Marshall in Oxford: little David beat Goliath, if we can believe the record; in part perhaps because Marshall was a home-boy, and the well-to-do undergraduates of those days started out hostile to George; there is also the fact gleaned from Henry George's biography that he slept miserably on that trip and the night before the debate. Playing the parlor game of Charles Lamb and William Hazlitt as to which characters in history one would like to meet, I would plunk for being present when Alfred Marshall debated Henry George.

the impression from autobiographies of such contemporaries as J. J. Thomson, the discoverer of the electron and Nobel Prize winner, that they had no great opinion of the economics being offered at that time in Cambridge.

IV. *We Happy Few*

If then Marshall and neoclassical writers have had influence upon the affairs of men, and I think they have had pronounced influence, we must regard these influencings as being indirect rather than direct.

For a long time John Maynard Keynes was known for one famous quotation, the casual remark: "In the long run we are all dead." Now that Keynes himself is dead, he is best known for a different quotation:

. . . the ideas of economists and political philosophers, both when they are right and when they are wrong, are more powerful than is commonly understood. Indeed the world is ruled by little else. Practical men, who believe themselves to be quite exempt from any intellectual influences, are usually the slaves of some defunct economist. Madmen in authority, who hear voices in the air, are distilling their frenzy from some academic scribbler of a few years back. I am sure that the power of vested interests is vastly exaggerated compared with the gradual encroachment of ideas. Not, indeed, immediately, but after a certain interval; for in the field of economic and political philosophy there are not many who are influenced by new theories after they are twenty-five or thirty years of age, so that the ideas which civil servants and politicians and even agitators apply to current events are not likely to be the newest. But, soon or late, it is ideas, not vested interests, which are dangerous for good or evil.

This is fine writing. And no doubt it is flattering to our egos. But is it really true? Keynes did not specify what academic scribblers he had in mind, and I am not sure how easy it would have been for him to do so. (Thus, when we see a politician favoring protective tariffs or a balanced budget, do we have to look for any profound analysis from some earlier thinker or can we not simply reflect that most people generate such notions almost unthinkingly? Yet, even if that is so, what are we to conclude in the case where we observe a politician favoring free trade or deficit-financing? The issue is certainly not a simple one.)

The leaders of this world may seem to be led around through the nose by their economist advisers. But who is pulling and who is pushing? And note this: he who picks his doctor from an array of competing doctors is in a real sense his own doctor. The Prince often gets to hear what he wants to hear.

Where does that leave us then as economists? It leaves us where

we ought to be. Our map of the world differs from that of the layman. Perhaps our map will never be a best seller. But a discipline like economics has a logic and validity of its own. We believe in our map because we cannot help doing so. In Frank Ramsey's beautiful quotation from William Blake:

"Truth can never be told so as to be understood and not be believed."

Ours is an uncertain truth and economic scholars are humble about its precision—but our humbleness is built out of knowledge, not out of ignorance.

Not for us is the limelight and the applause. But that doesn't mean the game is not worth the candle or that we do not in the end win the game. In the long run, the economic scholar works for the only coin worth having—our own applause.¹¹

¹¹ Lest I be misunderstood, I elaborate. This is not a plea for "Art for its own sake," "Logical elegance for the sake of elegance." It is not a plea for leaving the real-world problems of political economy to noneconomists. It is not a plea for short-run popularity with members of a narrow in-group. Rather it is a plea for calling shots as they really appear to be (on reflection and after weighing all evidences), even when this means losing popularity with the great audience of men and running against "the spirit of the times."

RESEARCH ON HOUSEHOLD BEHAVIOR

By ROBERT FERBER*

The purpose of this article is to survey the main empirical research of recent years on household behavior. Although the emphasis is on empirical work, principal theoretical developments are also reviewed, partly because of their relevance to an understanding of current thinking in the field and partly to place the empirical studies in proper perspective.

It should be stressed that this article relates to consumer behavior at the microeconomic level. Although various parts touch on problems of aggregation and of macroeconomic relations, comprehensive coverage of these areas is outside the present scope. Furthermore, the focus is on spending and saving behavior rather than on the income or other economic or noneconomic behavior aspects of the consumer. At the same time this article necessarily transcends the usual boundaries of economics, in view of the growing importance of other disciplines to this area, particularly marketing, sociology and psychology.

Virtually all of the developments covered in this article relate to the period since the Second World War. This hardly constitutes much of a limitation considering the tremendous amount of research that has taken place during this period. As it is, this material is so extensive and diversified that only the highlights can be covered in a relatively short article such as this.

The great bulk of studies of household behavior in the past fifteen years have dealt with one or more of the following aspects of the subject: (1) Theories of spending, or saving, behavior; (2) Influence of variables other than income on spending and saving; (3) Determinants of asset holdings; (4) Determinants of specific expenditures; (5) Decision processes.

This classification accordingly serves as the framework for this article. Admittedly, it focuses entirely on the determinants of household

*The author is research professor of economics, Bureau of Economic and Business Research, and professor of economics in the department of economics, University of Illinois. He would like to thank Margaret Reid, Marianne A. Ferber, and Walter McMahon for their helpful comments. He would also like to express his appreciation to Anne Harper for assisting with the preparation of the bibliography.

[This is the fourth of a series of survey articles for which financial support has been provided by the Rockefeller Foundation.—*Editor*.]

behavior, and ignores the two other basic aspects of this subject, namely, the effects of household behavior on other sectors of the economy, and the measurement of household behavior. The fact remains, however, that relatively little work has been done in these areas, despite their great importance. They are considered briefly in the final section, dealing with future directions for research.¹ Excluded also are those studies dealing with the purchase behavior of a particular population, or reference group, and studies dealing with the choice of brands or of shopping locations. Some of these studies are covered in connection with the determinants of specific expenditures. To cover all of them, however, is too much for this article, aside from the fact that these studies are primarily of a more routine nature.

I. *General Theories of Spending or Saving Behavior*

Three general theories currently exist on the determinants of total consumer spending: the *absolute income hypothesis*, the *relative income hypothesis*, and the *permanent income hypothesis*. Though radically different in interpretation, they nevertheless possess certain properties in common. One such property is their purported generality. Each has been used on time series as well as on cross-section data and to derive macro- as well as micro-relationships.² Each was advanced originally in terms of individual behavior and then generalized to aggregate behavior, sometimes with explicit recognition of the aggregation problem, and at other times largely ignoring it on the apparent presumption that nonlinearities or distributional effects are relatively unimportant.

Each hypothesis postulates a relationship between consumption and income, though the concepts underlying these terms may vary substantially. In other words, the primary concern is to isolate the influence of income, and occasionally of wealth, on consumer spending, holding constant the effect of other possibly relevant, less important variables—age, family composition, location of residence, education, etc. Each is the subject of wide controversy, receiving support from some empirical studies but not from others. Finally, each when first presented appears deceptively simple, at least in theory, but when it comes to implementation, proponents of the same hypothesis often

¹ Omitted also is the normative aspect of how households *should* behave. Hardly any empirical research has been devoted to this question, with the possible exception of exploratory studies in the measurement of utility. In its more pedestrian aspects, the normative question falls within the realm of home economics.

² In the latter case, the application has often been to groups of households rather than to individual households, particularly in the case of the permanent income hypothesis, on the ground that the importance of erratic factors is so great for individual households as to obscure more basic relationships.

disagree with each other on appropriate definitions and approaches. This will become clear from a consideration of each hypothesis in turn.

Keynes *GA. Absolute Income Hypothesis.*¹ "I. men are disposed, as a rule and on the average, to increase their consumption as their income increases, but not by as much as the increase in their income" [192, p. 96]. Whether or not this is the original statement of the absolute income hypothesis, there is no doubt that this statement by Keynes stimulated much empirical work to test this hypothesis and to derive "the consumption function." Many of these studies were carried out on time series, the general practice being to correlate aggregate consumption expenditures over time with aggregate disposable income and various other variables. They need not concern us here except to note that invariably they "corroborated" the hypothesis, producing very high goodness of fit (adjusted correlation coefficients of .98 or more), with current income accounting for the bulk of the variation in consumption, the average and marginal propensities being less than unity, and with the marginal propensity less than the average propensity.³ *GT 20*

One early modification of the absolute income hypothesis was brought about by a theoretical controversy regarding the existence of any automatic force to assure full-employment equilibrium. Keynes took a negative position, but others showed that a full-employment equilibrium position could exist if consumption expenditures depended on wealth as well as on income, the "Pigou real balance effect" [138].⁴ It was only in the postwar period that data became available to test the relevance of a wealth variable. Such tests as were made did tend to show that aggregate consumption was influenced by this variable, though nowhere to the extent of the influence of current income [69] [95]. It is pertinent to note, however, that the early postwar years were characterized by high asset-income ratios, low stocks of durables, and relatively little debt. }✓

At the micro level, many studies had been carried out prior to the advent of *The General Theory* but their focus invariably was on ascertaining budget relations for different groups of families or deriving Engel curves for particular components of expenditure.⁵ In retrospect, such of these studies as were applicable appeared to corroborate the absolute income hypothesis. Indeed, it was this hypothesis that served as the basis for the derivation of estimates of aggregate expenditures for different population groups in 1935-36, namely, by "blowing up"

³ For a summary of these studies to 1950, see Ferber [41]. An extensive bibliography of these earlier studies has been compiled by Orcutt and Roy [135].

⁴ For a somewhat different interpretation, see Hansen [71]

⁵ These are reviewed in Stigler [148]. A fairly comprehensive listing of these studies will be found in Williams and Zimmerman [169].

average consumption observed at each income level in the 1935-36 Consumer Purchases Study [161].⁶ The absolute income hypothesis also served as a basis for the derivation of aggregate forecasts of post-war consumption patterns, particularly the consumption patterns that might be expected under full employment [28].

In its empirical applications the absolute income hypothesis has generally followed one of two forms. One form has been to express the level of saving, or of consumption expenditures,⁷ as a function of income and of other variables, i.e.:

$$(1) \quad S = a + bY + cZ + u \quad \text{--- (1)}$$

where S represents saving, Y is income, Z is a conglomeration of other variables, u is a stochastic term, and the other letters represent parameters.⁸

The second form involves expressing the saving *ratio* as a function of the same independent variables, i.e.:

$$(2) \quad \frac{S}{Y} = a' + b'Y + c'Z + u' \quad \text{--- (2)}$$

Each of these forms has advantages and limitations. Thus, in equation (1) the marginal propensity is a constant and, if logarithms of the variables are used, the income elasticity is also constant, namely, b . Equation (2) does not possess this convenient property but may be more realistic for this reason. Parameter estimates based on equation (1) are subject to the danger of bias from two sources: the parameter estimates may be dominated by extreme values, and u is not likely to be independent of S . Expressing dollar variables in logarithms (assuming absence of negative values) removes this tendency somewhat, but not altogether. In actual practice, both forms have been used.⁹

{ Questions about the adequacy of the absolute income hypothesis arose because of its apparent inability to reconcile budget data on saving with observed long-run trends. Estimates of national saving and other aggregates derived by Kuznets [105] [106] and later by Goldsmith [65, Vol. 1, pp. 75-87] indicated that the aggregate saving ratio had

⁶ The actual aggregation procedure was more complicated, but was based on this principle.

⁷ It is perhaps needless to note that consumption functions and saving functions are the same, in theory, one being the complement of the other. However, substantial differences can be obtained in empirical work according to which term is being measured.

⁸ We shall follow the usual distinction between *saving* and *savings*, the former representing a flow, that is, the difference between income and consumption during a particular period, and the latter representing a stock as of a certain point in time. Unless otherwise specified, saving is defined as the amount set aside out of current income rather than as the net increment in wealth.

⁹ For applications of these functions at the microeconomic level, see Mendershausen [119], Klein [94] [96], Fisher [50].

remained virtually constant since the 1870's. Yet budget studies showed that the saving ratio rose substantially with income level. Since incomes have risen tremendously since the 1870's by almost any standard, this would suggest, according to the absolute income hypothesis, that the aggregate saving ratio should have moved up noticeably over

Increasing time
 B. *Relative Income Hypothesis*. (An answer to this apparent inconsistency is provided by the relative income hypothesis, which seems to have been first propounded by Dorothy Brady and Rose Friedman [14]. Its underlying assumption is that the saving rate depends not on the level of income but on the *relative position* of the individual on the income scale, i.e.:

$$(3) \quad \frac{s}{y} = a + b \frac{y}{\bar{y}}$$

y = current income
 \bar{y} = previous income

where s and y represent individual saving and income, respectively, and \bar{y} represents average income.

Much additional theoretical and empirical support of this hypothesis was provided by the work of Modigliani and of Duesenberry, carried out at about the same time [122] [35]. On a theoretical level, Duesenberry supplied psychological support for this hypothesis, noting that a strong tendency exists in our social system for people to emulate their neighbors and, at the same time, to strive constantly toward a higher standard of living. Hence, once a new, higher standard of living is obtained, as at a cyclical peak, people are reluctant to return to a lower level when incomes go down. In other words, people seek to maintain at least the highest standard of living attained in the past.)

(On the basis of this reasoning, Duesenberry inferred that from an aggregate time-series point of view the relative income hypothesis could be transformed into one expressing the saving rate as a function of the ratio of current income to the highest level previously reached, i.e.:

$$(4) \quad \frac{S}{Y} = a + b \frac{Y}{Y_0} \quad (\text{short run}) \quad a, b \text{ } \left. \begin{array}{l} \text{long run} \\ \text{short run} \end{array} \right\}$$

where Y_0 represents the highest level of income previously attained (after deflation for changes in prices and population).

The implication of this hypothesis is that the saving ratio in the long run is constant, independent of the absolute level of income, although in the short run (from one cycle to another) the rate depends on the ratio of current income to previous peak income.

One variation of this approach has been the suggestion by Davis: that previous peak consumption be substituted for previous peak income [33]. The rationale for this suggestion is that people become ad-

justed to a certain standard of *consumption*, rather than to a certain level of income, so that it is past spending that influences current consumption rather than past income. An additional argument for the substitution of consumption for income is that current income, referring to a period of one year or less, is likely to be less stable and less representative of a family's living standard than is current consumption [164, pp. 280-95].

The empirical support for the relative income hypothesis has proceeded along two lines. One consisted of showing that the aggregate relations of a form similar to (4) provide at least as good explanations and statistical "fits" to fluctuations in national personal saving over time as the various forms of the absolute income hypothesis [33] [35, pp. 89-92] [122, pp. 379-99]. Noteworthy in this respect was the finding of an independent evaluation that these functions yielded greater predictive accuracy outside of the period of observation than did various forms of the absolute income hypothesis [45].¹⁰ In addition, of course, there was the constancy of the aggregate saving ratio over time which fitted in with the relative income hypothesis.)

Second, a number of instances were demonstrated in which the relative income hypothesis was, and the absolute income hypothesis was not, able to explain differences in saving or consumption patterns observed in budget data. Thus, Brady and Friedman by this approach were able to reconcile the higher saving rates of village than city families at the same levels of income in 1935-36, and again in 1941; the similarly higher saving rates of farm families than nonfarm families in 1935-36, and also in 1941; and various geographical differences in saving rates in 1935-36 [14]. Dusenberry used this hypothesis to reconcile the fact that dissaving at a given level of income was less frequent in 1941 than in 1935-36, that Negro families saved more than white families in 1935-36 at the same level of income, as well as to explain geographic differences in saving rates [35, Ch. 4, 5]. Brady showed that family saving varied not only with family income but also with the income level of the community in which it resided [10].

Findings such as these do not necessarily serve to rule out the absolute income hypothesis, and it is still very much of an open question whether the facts do indeed conflict with the absolute income hypothesis or whether the hypothesis has been misinterpreted. A basic tenet of the hypothesis is the *ceteris paribus* assumption for all variables other than (current) income. Yet, data availability in empirical studies has been too restricted to allow other principal relevant variables to be

¹⁰ However, the most accurate predictions of all were obtained when the functions were transformed into first-difference form, and it was then of little consequence which functional form was used.

held constant; and if such variables are indeed not constant, failure of saving, or the saving rate, to fluctuate with income may represent simply the effects of these omitted variables. Thus, Tobin shows that the apparent failure of the absolute income hypothesis to explain Negro-white saving differentials at the same level of income can be reconciled if allowance is made for the smaller financial resources available to Negro families than to white families. Because of this difference in wealth, Negro families are unable to dissave as frequently or as much as white families at the same income level, and therefore require extra financial reserves to tide them over emergencies [154, pp. 145-49].

In a similar manner Tobin shows that wealth differentials may explain geographic differences in saving rates, and even the historical constancy of the saving ratio. The latter is based on the presumption that the substantial growth in asset holdings over time may have reduced the need for saving out of current income and contributed to raising the propensity to consume as real income increased. Admittedly, the evidence is rather sketchy, as is noted by Tobin [154, pp. 154-56] and is stressed by Milton Friedman [56, pp. 173-82]. However, if a variable such as wealth could be shown to have influenced the secular propensity to consume, the absolute income hypothesis could be vindicated.

C. The Permanent Income Hypothesis. (This most recent hypothesis on consumer behavior grew out of the rising concern regarding the adequacy of current income as the most appropriate determinant of consumption expenditures.¹¹ Particularly among nonwage-earner families income receipts vary substantially from period to period, while consumption outlays exhibit much greater stability. This led to the belief that people geared their expenditures to average actual and anticipated income over a number of periods rather than only to income received in the current period.) The central idea is as follows [56, p. 220]:

Consider a large number of men all earning \$100 a week and spending \$100 a week on current consumption. Let them receive their pay once a week, the pay days being staggered, so that one-seventh are paid on Sunday, one-seventh on Monday, and so on. Suppose we collected budget data for a sample of these men for one day chosen at random, defined income as cash receipts on that day, and defined consumption as cash expenditures. One-seventh of the men would be recorded as having an income of \$100, six-sevenths as having an income of zero. It may well be that the men would spend more on pay day than on other days but they would also make expenditures on other days, so we would record the

¹¹ For example, see Margaret Reid [142], Milton Friedman and Simon Kuznets [58].

one-seventh with an income of \$100 as having positive savings, the other six-sevenths as having negative savings. Consumption might appear to rise with income, but, if so, not as much as income, so that the fraction of income saved would rise with income. These results tell us nothing meaningful about consumption behavior; they simply reflect the use of inappropriate concepts of income and consumption. Men do not adapt their cash expenditures on consumption to their cash receipts, and their cash expenditures on consumption may not be a good index of the value of services consumed—in our simple example, consumption expenditures might well be zero on Sunday.

As is often the case with developments of this sort, a theoretical foundation for this hypothesis was developed more or less independently by two different people: by Milton Friedman and by Franco Modigliani, the latter with the collaboration of R. E. Brumberg and Albert Ando. The two versions are similar in principle, though different in certain respects. Whether it is because of its deceptively simpler formulation or because of its more provocative interpretations and assumptions, the Friedman form has gained wider attention. In what follows both forms are presented, with greater emphasis on the Friedman formulation.

✓ The permanent income hypothesis of Friedman may be said to rest on three fundamental tenets. First, a consumer unit's measured (observed) income (y) and consumption (c) in a particular period may be segregated into "transitory" and "permanent" components, i.e.:

$$(5a) \quad y = y_p + y_t \quad \checkmark \quad (1) \text{ ad}$$

$$(5b) \quad c = c_p + c_t \quad \checkmark \quad (2) \text{ ad}$$

Permanent income, say, in a given year, is the product of two factors: the wealth of the consumer unit, estimated as the discounted present value of a stream of future expected receipts, and the rate, r (or weighted average of a set of rates), at which these expected receipts are discounted [57].

The second tenet is that permanent consumption is a multiple, k , of permanent income:

$$(6) \quad c_p = k y_p \quad \checkmark \quad (3)$$

where k depends only on the interest rate, i , the ratio of nonhuman to total (nonhuman plus human) wealth, w , and a catchall variable, u , of which age and tastes are principal components. In other words, $k = f(i, w, u)$, but k is independent of the level of permanent income. It should be noted that consumption here is defined in the physical sense rather than in the monetary sense, i.e., as the physical consumption of goods and services. Durables purchased in a current period

are considered as saving to the extent that they are not used up in that period.

Third, transitory and permanent income are assumed to be uncorrelated, as are transitory and permanent consumption, and transitory consumption and transitory income:

$$(7) \quad r_{y_t y_p} = r_{c_t c_p} = r_{y_t c_t} = 0 \quad \dots \quad (4) \quad \text{fundamental}$$

As a result, a consumer unit is assumed to determine its standard of living on the basis of expected returns from its resources over its lifetime. These returns are expected to be constant from year to year, though in actual practice some fluctuation would result over time with changes in the anticipated amount of capital resources. The expenditures of the consumer unit are set as a constant proportion (k) of this permanent level of income, the value of k varying for consumer units of different types and of different tastes.¹² Actual consumption and actual income deviate from these planned, or permanent, levels to the extent that transitory factors enter in, e.g., a crop failure in the case of farm family income or unexpected medical bills in the case of spending. However, these transitory factors are essentially random and independent of each other, with the primary result of serving to obscure the true underlying relationship between the permanent components of income and of consumption.

[The Modigliani-Brumberg-Ando (MBA) formulation is essentially a "permanent wealth" hypothesis rather than a "permanent income" hypothesis, though in practice the two approaches converge.] In its most recent formulation, the household or consumer unit is assumed to determine "the amount available for consumption over life, which is the sum of the household's net worth at the beginning of the period . . . plus the present value of its non-property income . . . minus present value of planned bequests" [123, p. 78]. The amount allocated to consumption (defined in the same manner as by Friedman) is a certain proportion of these resources. Actual consumption, however, differs from this allocated amount by transitory expenditures and by certain stochastic factors (v), i.e.:

$$(8) \quad c_t = k^* x_t + v_t$$

Thus, this relationship is essentially the same as that derived by Friedman [by substituting (6) into (5b), with k^* in (8) corresponding to the product of r and k]. Note, however, that the variables in equation (8) have time subscripts whereas those of Friedman's do

¹² A very similar formulation is provided by William Hamburger [70]. He postulates total current expenditures of consumers to depend principally on tastes, the interest rate and the discounted value of lifetime resources, the last being determined by the sum of wealth and a multiple of his current wage rate.

not. In the MBA formulation, k^* is assumed to vary explicitly with the age of the consumer unit, as is x , and possibly with other factors, such as family size. In the Friedman formulation, k is a constant for the same consumer unit over time.¹³

The MBA formulation is also more flexible in that the possibility is considered that transitory income and transitory consumption may be related to each other. In that event, Modigliani and Ando show that equation (8) turns into the following form:

$$(9) \quad c_t = f(k'_t, x_t, y_t)$$

so that current income as well as permanent income enter into this relation as determinants of current (observed) consumption. In their empirical work, however, Modigliani and Ando do not seem to have tested this relation.

In either formulation the central tenet is the assumption that the proportion of permanent income saved by a consumer unit in a given period is independent of its income (or its resources) during that period, and furthermore that transitory incomes may have no (Friedman) or little (MBA) effect on current consumption. ✓

✓ Clearly, from an empirical point of view, this is a very difficult hypothesis to test, because of the difficulty of measuring permanent income and permanent consumption. Nevertheless, the permanent income hypothesis is analytically a very rich one and lends itself to a number of significant inferences regarding individual and aggregate behavior.) This is not the place to develop these inferences, particularly since they have been developed elsewhere [56, Ch. 3, 7] [124] [123, esp. pp. 74-109] (However, one theoretical inference of this hypothesis deserves special mention because of its basic importance to the empirical tests. Under the permanent income hypothesis, the slope of the relation between observed consumption and observed income, namely (assuming linearity) b in: $c = a + by$, can be shown to be equivalent to kP_y , where P_y is the ratio of the variance of the permanent component of income to the total variance of income, i.e.:

$$P_y = \frac{\sum (y_p - \bar{y}_p)^2}{\sum (y - \bar{y})^2}$$

Since k is constant, by assumption, this means that fluctuations in the slope of measured income reflect fluctuations in the relative importance of the permanent component of income. Furthermore, R_y is equivalent to the income elasticity of consumption, if the elasticity is estimated at the sample means and if the transitory components of both income and consumption average zero. The significance of this be-

¹³ Although k may vary among consumer units, as noted previously, i.e., $k = f(i, w, u)$.

comes clear when we list the principal empirical results and observations advanced to support the permanent income hypothesis. ✓

✓ 1. From time series aggregates, Friedman notes that the following findings are in accord with the hypothesis [56, Ch. 5]: (a) The marginal propensity to consume is invariably less than the average propensity to consume. (b) The ratio of permanent consumption to permanent income, k , appears to have been constant since at least 1897, after allowance for variability in the observed consumption-income ratio due to transitory factors.¹⁴ (c) The income elasticity of consumption tends to rise as the period of observation to which a consumption function is fitted increases, thus confirming that transitory factors become less important over longer time spans. (d) Marginal propensities estimated from data deflated for price or population changes are less than those estimated from the corresponding undeflated data: permanent components are more important in the latter case because of the general positive correlation among output, prices and population.

2. From cross-section budget data, Friedman notes that [56, Ch. 4]: (a) Despite observed inequality of income distributions on a cross-section basis, long-run trends indicate that the income distribution is becoming, if anything, more equal—thereby suggesting that measured income is not a valid measure of wealth. (b) The average propensity to consume has been relatively constant in budget studies covering ✓ different times and different groups. Furthermore, the stability in the average propensities, and the values of less than unity of the income elasticities, contradict the stability of these cross-section relations—suggesting that the consumption-income ratio declines as income rises, which is inconsistent with the time-series aggregates. (c) Income elasticities are less for the United States than for Great Britain or Sweden, suggesting that transitory factors are more important in the United States, as one might expect. (d) The income elasticity, as well as the marginal propensity and k , are all lower for farm families, and for non-farm and own-business families, than for other nonfarm families, in accord with the hypothesis. (e) Consumption-income regressions for groups of families classified by income change have steeper slopes than the over-all regression: the transitory component is smaller for income-change classes. ✓

✓ 3. Turning to work other than Friedman's, P_y estimated from income data for the same consumer units over time yields consistent results for different groups and different time periods. Such estimates also corre-

¹⁴ The allowance is rather arbitrary—seeing whether most of the annual points fall within 5 percentage points of a line going through the origin of the consumption-income graph and the long-run average of this ratio, .877. On the other hand, as Friedman notes, secular constancy of k is not an integral part of the permanent income hypothesis.

spond with estimated income elasticities from budget data, which also estimate (independently) P_y [143].

4. Classification of families by income change appears to result largely in a manifestation of transitory income, rather than expenditure lags behind changes in permanent income; the consumption-income ratio varies most between years for families with substantial income change [146].

5. The estimated income elasticity for all households exceeds the weighted average of income elasticities for relatively homogeneous groups of households—variation due to transitory factors is less important in the former case [38] [123, pp. 123-66].¹⁵ Furthermore, no systematic association is apparent between mean income and the consumption-income ratio for most criteria; education is a notable exception.

6. Increasing the importance of transitory income by classifying families by current income categories reduces income elasticity estimates—transitory components are more important among these presumably more homogeneous subgroups [37].

7. Groups with the more variable incomes have higher saving ratios [53, pp. 229-63].

8. The effect of age, or life cycle, is supported by the fact that the observed saving ratio is low for young age groups, highest in the later earning stages, and negative or very low in retirement [124]. ✓

✓ Despite these seemingly impressive arguments, the permanent income hypothesis is by no means established. Indeed, the evidence to the contrary seems at least as impressive. This opposing evidence, like the arguments for the theory, covers both theoretical and empirical considerations. On a theoretical plane, question is raised regarding the validity of the two central tenets of the theory, namely, the independence of k of the level of income, and the lack of correlation between transitory consumption and transitory income. Thus, Friend and Kravis note that the permanent income hypothesis implies "that low-income families will have no greater preference for purchase of future goods than will high-income families" [59 p. 538] while Duesenberry makes a similar criticism [36]. Such a concept they find to be seriously deficient on purely deductive grounds because of the very different kinds of pressures and motivations acting on families at different income levels. ✓

In a similar fashion, the assumption of a zero marginal propensity to consume out of transitory income is questioned, partly on the basis that low-income families are under strong pressures to spend any un-

¹⁵ "Relatively homogeneous groups" means households classified by characteristics unrelated to transitory factors, and for which permanent and transitory incomes are uncorrelated. Classifying criteria used were city size, education, occupation, age, tenure.

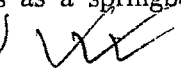

expected income to meet current needs [59, pp. 539-41], and partly because of the very unequal distribution of wealth which mitigates against dissaving by low-income families to maintain consumption in the face of temporary declines in income [156, p. 451].

Criticism of the permanent income hypothesis on empirical grounds has followed two lines. One line has been to note that much of the evidence advanced is either inconclusive or is not inconsistent with other principal hypotheses. Thus, under the absolute income hypothesis one would also expect the marginal propensity to consume to be less than the average propensity, groups with more variable incomes to have higher saving ratios, and consumption-income regressions for groups of families classified by income change to have steeper slopes than the over-all regression. In addition, as was noted previously, Tobin has suggested how the constancy of the long-run propensity to consume might be reconciled with the absolute income hypothesis. Furthermore, the interpretation given by Friedman to many of his test results is not the only possible interpretation and is at times subject to considerable doubt [63] [72] [156], though some of the evidence can apparently be interpreted only in terms of it [143].

From a more direct point of view, various test results have been advanced as contradicting the permanent income hypothesis. Thus, Friend and Kravis show that the same variation in the saving rate occurs when families are classified by constancy of three-year income as by constancy of one-year income, based on recall data obtained in one-time interviews [59, pp. 544-45]. In addition, they show that saving rates of different occupational groups appear to be closely correlated with the average income of these groups [59, p. 546] [60, pp. 272-73].

To test the zero propensity to consume out of transitory income, Bodkin [8] analyzed by correlation methods the extent to which consumption expenditures were made out of unexpected dividends paid in early 1950 out of National Service Life Insurance. This study yielded not only a statistically significant propensity but a propensity to consume out of these dividends much higher than out of regular income.¹⁶ On the other hand, Krein [104A] obtained a low marginal propensity to consume out of restitution payments made by Germany to former citizens in Israel. However, these payments could hardly have been unexpected.

¹⁶ Friedman attempts to reconcile the results with the permanent income hypothesis, on the assumption that these dividend receipts might have been anticipated and/or they created expectations of future dividend receipts, so that this windfall becomes a proxy for permanent income [57A, pp. 191-206]. In view of the circumstances surrounding the payment of these dividends, however, such an assumption is highly questionable. A more likely explanation is one offered by Margaret Reid (unpublished) that the receipts may have stimulated purchase of homes, thereby setting off a long-run program of saving but a short-run program of spending.

Admittedly, these negative findings are themselves subject to question. For example, the reliability and representativeness of budget data collected in a partial wartime period such as 1950 is a matter of doubt [136]. In any event, the permanent income hypothesis is far from proven. However, whether or not the permanent income hypothesis turns out to be valid, there is little doubt that, to quote Tobin, "This is one of those rare contributions of which it can be said that research and thought in its field will not be the same henceforth" [156, p. 447]. Most of all, it has led to widespread recognition of the possible effects of variability in income on consumption patterns and has provided a theoretical basis for measuring these effects as a springboard for a more realistic theory of consumer behavior.¹⁷) 

III. Influence of Variables Other than Income

A number of studies have been undertaken in recent years to ascertain the effect of particular variables entering into the *ceteris paribus* assumption of the consumption, or saving, function. These studies have focused generally on three sets of variables: socio-economic characteristics of the household, particularly age and life cycle; financial characteristics; and attitudes and expectations. Principal work in each of these subareas is reviewed in this section.

Focus on the *ceteris paribus* assumption does not necessarily abstract from the effect of income, for two principal reasons. First, most socio-economic as well as other variables are related to income. Since most of these "*ceteris paribus* studies" are carried out either by cross tabulation or by some multivariate method such as analysis of variance or multiple regression, part of the effect attributed to the particular variable may actually be due to income, particularly when interactions and other nonlinear effects are present. Second, to the extent that the permanent income hypothesis is valid, even holding constant the effect of current income (the only basis on which income data are available) means that these other variables act to some unknown extent as proxies for permanent income, thereby leading to biased estimates of the effect of these other variables. The fact remains, however, that the *ceteris paribus* variables are of interest in their own right, and even biased effects can be useful.

A. Socio-Economic Characteristics

Virtually every budget study presents breakdowns of expenditures and data on such characteristics as age, education, family size, etc.

¹⁷ For an interesting application of the permanent income hypothesis to analyzing consumer behavior, see the study by Jacob Mincer relating labor activity to family income and consumption [121].

However, the isolation of the effects of these variables on total expenditures or on total saving has received relatively little attention until recently. The availability of the Surveys of Consumer Finances and the various BLS consumer expenditures studies, particularly the 1950 study, and the advent of the relative income and permanent income hypotheses have spurred new interest in these variables. As a result of the latter interest, various studies have attempted to derive saving-income ratios for different population groups. One such study, by Harold Watts, ascribes a central role to occupation and education in the determination of expenditures [165]. Watts attempts to explain expenditures on the basis of a person's expected future income, which is related to a "cross-section profile" holding occupation, education, and age constant. Among other things, he finds that, at a given level of income, those with more education expect higher incomes and spend more.

An attempt by James Morgan to isolate the effects of socio-economic factors on the saving ratio [126]—in this study, saving is defined as changes in net worth, including purchases of durable goods—uses residuals from regressions of saving on income to examine the effect of a large number of additional socio-economic variables, partly by further regressions and partly by application of analysis of variance.¹⁸ Among other things, these results show that the self-employed, including farmers, had very different saving patterns from other families, that home owners saved more than renters, that dwellers in open country areas saved more than metropolitan dwellers, and that life cycle was highly relevant to understanding saving patterns.

In the case of family size, considerable attention has been given to the problem of allowing for variations in expenditures due to differences in family size, either by deflating by a family-size variable or by including family size as a separate factor. The principal work in this area has been concerned with converting family size into an equivalent-adult unit basis. This problem goes back many years, and an extensive literature has grown up around it, with more recent emphasis on the incorporation of this adjustment within a multivariate framework (for example [140, Ch. 9] [55]).

Attention has also been given to the effect on saving and spending of owning an unincorporated business. Various studies in recent years have thrown considerable light on the saving habits of unincorporated business families, as well as on aggregate saving trends in this area

¹⁸ Aside from purely statistical considerations, the validity of this methodological procedure depends on whether the absolute income hypothesis or the permanent income hypothesis is correct. If the latter is the case, the procedure is a biased one because, as noted previously, only measured income is then held constant while the effect of permanent income is intermingled with the other socio-economic variables. See Friedman [56, pp. 86ff.].

[60] [101]. Thus, both Klein-Margolis and Friend-Kravis show that such families have much larger than average negative saving at low incomes and much higher than average positive saving at high incomes than other families, and that the same is true of both farm and non-farm entrepreneurs. Friend-Kravis show that the self-employed exhibit much the same consumption pattern as that of other families; though another study by L. R. Klein suggests that the self-employed are more frequently home-owners and tend to spend less for rental costs and more for household operations than families of salaried professionals and officials [99, pp. 331-35]. Klein also shows that the self-employed save more than other families principally because of their business saving; they do not save appreciably more in other forms.

Age and the Life Cycle. Perhaps the main analytical work in recent years relating to socio-economic characteristics has been with age and the life cycle. Although various early budget studies were concerned in part with the influence of age in one or more of these respects, it was primarily the 1935-36 Consumer Purchases Study with its extensive tabulations that served as a springboard for analysis of the influence of the age factor on consumption. In that study, attempts were made to examine variations in income and in consumption not only by different age groups but by different family types, reflecting to a large extent different stages of the family life cycle [158] [159].

The substantial variations observed in income and consumption by age and family composition led to further study of these variables in the postwar years. The initial studies focused primarily on the effects of age or of family composition. Many of these studies were carried out at the Survey Research Center of the University of Michigan, based on data collected in the Survey of Consumer Finances. Using these data, Janet Fisher was able to develop much useful information on the role of the age factor in consumer behavior [50] [51] [52]. These studies provide empirical data on the manner in which income increases from youth to about middle age and then declines thereafter (though with considerable variation by occupation and wealth); on the manner in which liquid assets rise from youth through middle age and decline thereafter; and on the different purchasing patterns of families in different age levels. Especially notable in the last category is the tendency for younger families to be heavy purchasers of durable goods even though they may have to dissave to do so, whereas older families with the necessary assets make relatively few durable goods purchases.¹⁹

¹⁹ Of particular interest from this point of view is the article by Dorothy Brady on the influence of age on saving and spending patterns [11]. More recently, a wealth of descriptive data on the consumption patterns of the aged will be found in the study by Sidney Goldstein [66].

In a very interesting exploratory study of the determinants of saving, Dorothy Brady finds that to a large extent age comparisons of saving rates are confounded with the effects of income changes, so that "the variation among the age groups in expenditures and saving within the current income bracket will accordingly be a reflection of changes in the direction and magnitude of income . . ." [12, p. 193]. Holding income constant, saving is found to increase uniformly as the age of the wife rises. In addition, Brady shows that family saving is influenced not only by socio-economic variables such as age, family size, and occupation, but may also be influenced substantially by the general level of income in the community where the family resides.

These and other results on the effect of family composition on spending and saving have brought into focus the importance of a life-cycle variable, a variable which would reflect the simultaneous influence of a number of different socio-economic characteristics.²⁰ This interest led, among other things, to the convening in 1954 of a conference by Consumer Behavior, Inc., on the life cycle as related to economic, marketing and sociological behavior of consumer units. The volume that grew out of this conference provides a wealth of data on the subject [23], ranging from provocative discussions of the role of age and U.S. culture on consumer purchases (by David Riesman and Howard Roseborough) to the first really thorough empirical study of consumer finances over the life cycle (by John B. Lansing and James N. Morgan). The latter study is particularly noteworthy because it uses as the basis for the analysis a classification of consumer units by stage of life cycle rather than by age alone, as was the case for virtually all of the previous studies. The article demonstrates the analytical values of such a classification and presents empirical data on the manner in which income, spending and assets vary over the life cycle. Related studies in this volume present information on the manner in which purchasing interest and purchasing trends vary by the life cycle, and on the possible impact of the life cycle on advertising [5] [120].

Some studies have also been conducted on the effect of the life cycle on consumer behavior in Great Britain. Thus, Harold Lydall has traced the life-cycle pattern in income receipts, in savings, and in net worth, finding the pattern roughly similar in Great Britain to that in the United States [112].²¹ At the same time, net worth does not appear to decline as much in Great Britain after income has turned down. In addition, a comparative study by Janet Fisher shows that durable-goods purchases were much more prevalent in the United States than

²⁰ Actually, life cycle as a variable had for some time previous been a principal topic in the study of the sociology of the family, and had also been of interest in studying the spending patterns of farm families. For example, see Kirkpatrick [93], Glick [64].

²¹ Although life cycle is the focus of this study, only age is used as a classifying variable.

in Great Britain for the same age groups, and that incomes began to decline at an earlier age in the United States than in Great Britain [52, pp. 33-35].

B. Financial Factors

Income Change. A number of studies of the effects of income-change have been made in the postwar years. The findings of these studies are generally similar, but the interpretation of the findings has differed at times substantially, as noted in the discussion of the permanent income hypothesis. Thus, in several studies based on data collected in the Surveys of Consumer Finances, high saving rates are found to be associated, at the same income level, with recent increases in income while those whose incomes have fallen tend to save less. Dissaving was more common among those whose incomes had either declined or risen substantially than among consumer units with relatively stable incomes. Furthermore, an inverse correlation was found between the purchase of durable goods and saving, consumer units having major outlays for durable goods being much more likely to dissave [82] [83] [87] [98] [126]. Morgan notes that the effect of income change varies with asset ownership: among those with small amounts of liquid assets, saving does not vary so much with income change [96, p. 124].

Similar findings on the effect of income change on spending behavior were obtained by Ruth Mack in analyzing budget data of 600 farm families [114]; and she suggests that the effect of changes in income is likely to differ for different expenditure categories. On the other hand, as noted earlier (p. 30), Margaret Reid shows that the same data can be interpreted as highlighting the importance of transitory income in distorting expenditure-income relationships.

The incorporation of income-change as a variable in multiple regressions explaining household saving rates leads to mixed results. Studies by Klein, Morgan, and Katona indicate that the effects of this variable may interact partly with income expectations and partly with liquid assets [82] [94] [96] [98]. Furthermore, the effect may be asymmetrical, being more pronounced for income decreases than for income increases. Households experiencing income decreases and who expect further decreases appear to save more, at the same level of income, than households experiencing decreases but expecting an upturn in the near future [94, p. 446].

In a unique study of short-run effects of income change upon saving, savings, and expenditures in a relatively isolated New England community, George Brinegar finds that household behavior serves to amplify rather than to dampen the effects of income change upon purchases of goods and services [17] [18]. Thus, following a sharp income

decrease milk purchases first declined, then rose above the earlier level, and finally leveled off. In addition, correlations between payrolls and bank balances indicated greater stability between payrolls and savings-account balances than between payrolls and saving in these accounts, thus providing some support for the Pigouvian analysis of income determination.

(*Wealth*. The relevance of wealth to consumption and saving has been recognized in the theoretical literature for some time. As noted earlier, Pigou [138], as well as Lerner in a different sense [110, pp. 44-49], had stressed the importance of increases in wealth in maintaining full employment by causing the consumption-income schedule to shift to the right. Tobin has suggested that increases in wealth may be responsible for the constancy of the aggregate propensity to save over time. Ackley has ascribed a crucial role to wealth in the determination of the cyclical consumption function [1]. In addition, wealth, it will be recalled, plays a central role in the permanent income hypothesis: In the Friedman formulation the ratio of permanent consumption to permanent income is assumed to rise with increases in the ratio of wealth to income; in the MBA formulation, wealth serves as the basis for estimating permanent income.) However, empirical work has been, and continues to be, hampered by lack of data. This has been particularly true with regard to wealth and individual behavior, since data on liquid assets have been available only since the Second World War.

Although not conclusive, the weight of empirical evidence points to a positive, though erratic, relationship of liquid assets to consumption and saving, at least in the postwar years. Under the much less prosperous prewar conditions it is doubtful whether liquid assets exerted much influence on the consumption-income relationship, at least in the aggregate [26]; on a cross-section basis there do not seem to be any data. In the postwar years, the effect of liquid assets appears to have varied with time. A strong positive relationship with durable goods expenditures existed in the late 1940's and a much weaker effect in the early 1950's [96].

As a general rule, the saving rate for individual households appears to vary inversely with the ratio of liquid assets to income, and the influence of liquid assets on saving tends to diminish as the level of income rises [94] [95, pp. 210-27]. Households with a given amount of liquid assets that experience a decline in income tend to save less than households with the same income decline but with less liquid assets, or than households with the same amount of liquid assets but no income decline.

✓ In his study, Morgan found the liquid-asset effect to interact with income-change, the saving rate increasing with liquid assets for those

experiencing a substantial income increase, and the saving rate varying inversely with liquid-asset holdings among those experiencing substantial income declines [126].

Various students of the problem have suggested that net worth is a more relevant concept than liquid assets [113] [155]. This concept is also much closer to the definition of wealth in the MBA formulation of the permanent income hypothesis, in which wealth plays a basic role. Unfortunately, data on net worth are difficult to collect, and hypotheses based on net worth or on total resources have yet to be subjected to direct examination.

C. Expectations and Intentions-to-Buy

Although the role of expectations in consumer behavior has been discussed in the economic literature for many years, empirical research in this area has been purely a postwar development, and is attributable largely to the activity of one man, George Katona. His interest in economic behavior supplemented by a strong psychological background led him to stress, in the 1940's, the importance of expectations and attitudes in a high-level economy. He noted the importance of studying the factors underlying decision processes in economic behavior as well as the growing discretionary aspects of consumer spending, in the case of which attitudes and expectations might be expected to exert a dominant role [81]. Such factors influence *willingness* to buy, which for spending and saving other than that which is habitual would seem to be about as important as *ability* to buy.²² With the aid of data collected under his supervision in the annual Surveys of Consumer Finances, he has been able to present considerable support for this point of view, showing that durable goods purchases were related to a number of individual attitudes as well as to an index of attitudinal variables [90, pp. 91-106].

On the basis of such analyses, Katona and his associates at the Survey Research Center were able to conclude that "motives, attitudes and expectations often change at about the same time and in the same direction among large groups of consumers. Such changes commonly occur prior to changes in the rate of postponable spending and of saving" [85, p. 67], and hence attitudinal data were valuable for predicting consumer spending and saving behavior. As a result of these studies the Survey of Consumer Finances has been collecting such data every year and using them as a basis for analyzing and also predicting consumer behavior.

Data on intentions-to-buy were also collected in the annual Surveys

²² The main theoretical arguments are presented in Katona's early volume [84, pp. 63-81]. Also, see the study by George Katona and Eva Mueller [88].

of Consumer Finances, as part of the attitudinal section. It soon became evident, however, that not only did these data differ conceptually from that obtained with the other attitudinal questions (representing in effect an *ex ante* expression of consumer purchases) but exhibited at times a marked relationship to actual purchases apart from the attitudinal data. Such relationships were apparent both over time and on a cross-section basis, even though these intentions referred to a year or more ahead [109, pp. 405-40]. In addition, experimentation with the collection of plans-to-buy data on a quarterly basis showed that meaningful quarterly data could be collected and, furthermore, that an even more marked relationship existed between plans to buy reported quarterly and later purchases [43, pp. 42-51] [42].

Considerable additional support for the value of plans-to-buy data has been provided by a project of the National Bureau of Economic Research, under the direction of F. T. Juster, to analyze the value, as a forecasting tool, of buying plans as reported by Consumers Union subscribers. Although Consumers Union subscribers are not typical of the total population, and although buying plans were collected on an annual basis, year-to-year changes in buying plans for selected major durable goods were found to foreshadow closely corresponding changes in actual purchases for the postwar years [77] [78]. In addition, these studies indicated that plans-to-buy data made a net contribution to predictive accuracy even after income was taken into account [76].

Partly as a result of these findings and partly because of the inter-correlation between plans to buy and attitudinal variables, a lively controversy has arisen regarding the relative superiority of these two types of data for forecasting purchases. Katona and some of his associates at Michigan maintain that attitudinal data provide insight into underlying motives and buying forces apart from socio-economic factors (age, income, wealth, etc.), and that such information can help improve forecasts. Others feel that plans-to-buy, though perhaps not as fundamental in a psychological sense, is the relevant overt variable for forecasting purposes, and that once such data have been taken into account, no net additional contribution can be expected from information on expectations or attitudes.²³

To date, the empirical tests provide strong evidence in favor of the second hypothesis. After reviewing the evidence then available, the Federal Reserve Consultant Committee on Consumer Survey Statistics under the chairmanship of Arthur Smithies concluded, in 1955, that "buying intentions, properly interpreted, appear to have predictive value. . . . Other attitudes are highly correlated with buying intentions, both over time and as among spending units, and there is so far no con-

²³ An excellent source for recent arguments and evidence pro and con is [162].

vincing evidence that they make an independent contribution to ability to predict . . ." [160, pp. 137-38]. Klein and Lansing found plans-to-buy to help significantly in multiple regressions discriminating between buyers and nonbuyers of durable goods—in addition to age, income, and marital status—while other attitudinal variables were either not effective or much less effective [100, pp. 115-26]. In a fundamental test, Tobin showed by regression analysis that plans-to-buy, in addition to socio-economic variables, made an appreciable net contribution to explaining durable goods purchases whereas this was not true of an attitudinal index; and, when combined in the same equation, plans-to-buy was significant, but not the attitudinal index [157]. Similar results were obtained by Okun [133].

Eva Mueller, though espousing the other side, shows that buying intentions but not an attitudinal index contribute significantly to multiple regressions explaining major durable-goods purchases [130]. The only evidence to the contrary presented so far is also in this study, which shows that an attitudinal index contributes more than buying plans, or than the same index including buying plans, to explaining aggregate semi-annual fluctuations in durable goods expenditures from 1952 to 1957. However, this test is not as comprehensive as Tobin's, including only income as an independent variable and making no allowance for heteroscedasticity.

The findings regarding the value of buying intentions as a predictive tool have been impressive enough that such data are now collected on a continuing, short-run basis. Consumer spending plans for major durables and other large expenditures have been collected bimonthly by telephone by the National Industrial Conference Board since 1958 [27], while the Federal Reserve Board in conjunction with the U. S. Bureau of the Census has been collecting quarterly buying intentions data on a much more comprehensive basis since 1959 [167].

Attitudinal data have not been ignored. Indeed virtually everybody is agreed that "the primary reason for collecting data on psychological factors influencing behavior is to improve the diagnosis of the prevailing situation" [79, p. 455]. Many of the studies reviewed here, particularly those of Katona and Mueller, have shown how expectations and attitudes are related to buying plans and to economic events, and have thrown light on their nature and characteristics.²⁴

III. *Determinants of Asset Holdings*

The growing stock of consumer assets has led to investigation not only of the influence of assets on saving behavior but also on the fac-

²⁴ In the former respect, see in addition to the previously cited publications, Katona [86] and Calla Van Syckle [163]. In the latter connection, see Ferber [44] and Katona [80].

tors associated with holding particular assets. With these more recent studies, the focus shifts from flows out of income to the investment decisions of the household and to explaining differences in the total stock of assets and their distribution among households and over time.

Reasons for holding particular types of assets have been discussed in the theoretical literature for some time [e.g., 92, Ch. 16]. More recently, Katona has attempted to merge these reasons with motivational and other psychological factors as a basis for empirical study [84, pp. 98-107].

Empirical studies are, as yet, relatively few. In a comprehensive study of the factors influencing the composition of the "capital account" of the household (essentially financial assets, durables, business capital), Watts and Tobin concluded that "households tend to maintain some sort of balance in their capital accounts both between assets yielding direct service and financial assets, and between liquid funds and liabilities" [166, p. 48]. Ownership of different assets was positively correlated, while assets and debts were negatively correlated: apparently as households moved up the economic status scale, more of all kinds of assets were acquired and debt was reduced.

By means of a series of multiple regressions on the 1950 Consumer Expenditures data, Watts and Tobin find the composition of particular portfolios to be influenced by a number of "fundamental but unobserved measures of social, economic, and biological, and environmental characteristics" [166, p. 48]. In particular, households headed by people with more education tended to have larger stocks of assets and lower debt, with income and other relevant variables held constant. Older households had less invested in durables and less debt as well. Occupational differences are pronounced, though erratic. Larger families generally had more in durables and less cash than other households. Regional and city-size differences were also apparent. Higher-income households had more in financial assets and less in durables.

Despite the large number of significant relationships, however, in most instances less than 10 per cent of the variation in the dependent variable was explained.

In a study of factors influencing the holding of liquid assets by British households, Lydall finds total wealth (measured as net worth) rather than income level to be the primary determinant of such holdings [113].²⁵ Applying multiple regressions to data from the Surveys of Consumer Finances, Harold Guthrie shows that liquid assets relative to income tend to rise with age and fall as the size of the consumer

²⁵ It is not clear, however, to what extent this finding is affected by the fact that liquid assets averaged over-all about one-fourth of net worth, but over 100 per cent in the lower net-worth classes.

unit increases. In addition, the liquid-assets ratio is higher for those who appear to have permanently depressed incomes and is less for those anticipating income increases [67].

Two other U. S. studies, by Butters *et al.* and Claycamp, found that the proportion of total assets held in liquid form declined substantially as wealth increased [19, pp. 299-316] [25]. The proportion of assets in liquid form also declined with income level, but a multiple regression study including both income and total assets indicated, as in the case of Lydall's study, that wealth was by far the dominant factor [25, Ch. 4].

Using data from the Consumer Savings Project,²⁶ Claycamp applied multiple regression analysis to test the relevance of a wide range of socio-economic and psychological variables to the proportion of total financial assets held in variable-dollar form, that is, assets whose value fluctuates with changes in prices (common stocks, marketable bonds, real estate, etc.). Age, home ownership, total assets, and occupation were significantly related to various forms of this variable-dollar ratio. Attitudinal variables, such as price expectations and other economic expectations, were not significant.

A major part of Claycamp's work was the investigation of the apparent lack of substitution between different types of assets. Such a lack of substitution had been noted by Guthrie between liquid assets and equity in homes; and he had suggested that "consumers do not shift between asset forms while maintaining some normative level of security in total wealth" [67, p. 478]. Tobin and Watts had also advanced the same idea with their hypothesis that consumers, in the handling of their capital accounts, attempted to balance assets and debts against each other [166]; while in a more recent study Phillip Cagan found an absence of substitution between pension contributions and other savings [20].

Claycamp's investigation of the frequency of different asset holdings provided strong support for this phenomenon, extending it to different combinations of 13 assets and debts, two or more at a time, using ownership frequencies and dollar amounts in turn. The results led to the so-called "independence hypothesis," namely, that "there is no significant difference between the actual proportion . . . owning a combination of holdings and the expected proportion which is found by multiplying each of the proportions in the combination" [25, p. 1]. Confirmation of this hypothesis would have major implications for economic analysis.

Various studies have been made by Kreinin with Survey Research

²⁶ Sponsored by the Inter-University Committee for Research on Consumer Behavior with financial assistance from the Ford Foundation and the U.S. Department of Agriculture.

Center data of the factors influencing ownership of specific assets, notably, liquid assets, life insurance, and common stock [102] [103] [104]. In these studies, which were carried out by analysis of variance, a number of socio-economic factors were found to be associated with ownership of these assets, particularly income and occupation. In the case of liquid assets, age and region were also significant; while education and liquid assets appeared to influence stock ownership. In the latter case, an optimistic outlook and willingness to take risk also showed some relationship to the dependent variable. In all of these studies, however, price expectations were not significantly related to the dependent variable, though other attitudinal variables were significant.²⁷

IV. Determinants of Specific Expenditures

Two different lines of approach have been used to ascertain the factors influencing the consumption of specific consumer products, reflecting the conceptual equality between purchases of goods by consumers and sales of these goods by retailers or manufacturers. One approach has attempted to explain static differences in product purchases of different households in terms of household characteristics, largely to the exclusion of prices and other market variables; while the other approach has attempted to explain temporal differences in aggregate sales in terms of market variables, largely to the exclusion of household characteristics (though aggregate income does appear in such functions).

Paralleling the consumption function, the first approach has been characterized by the search for so-called Engel curves—relationships between specific expenditures (or forms of saving) and income level, holding other relevant variables constant. The second general approach has utilized sales data and related information from industry sources. This approach has necessarily had to be aggregative in nature and, for this reason, has generally focused on the derivation of time-series relationships; it is exemplified by the search for demand curves, to ascertain how sales fluctuate in response to changes in price, holding other relevant factors constant.

²⁷ Unfortunately, the method used in these studies is subject to serious question. In each case, the analysis of variance was carried out by treating the cell means as the unit of observation rather than the individual consumer unit. Since the cell sizes in consumer surveys are decidedly unequal, such a procedure is an immense time saver. However, the procedure is also likely to distort seriously the significance of different factors, particularly of interaction effects, since the variance among the cell means is treated as equivalent to the random sampling variance. Some experimental computations made by the writer indicate that such an assumption is clearly unjustified, and that the use of the individual consumer unit as the unit of observation is likely to produce very different results, especially bringing out unexpected significant variables and interaction effects.

Empirical work on both approaches had its beginning about the mid-nineteenth century, with the work of Engel on household budgets and, some time later, with the work of a number of U. S. and British statisticians on demand relationships.²⁸ Since then empirical studies in both areas have multiplied enormously, spurred by the growing interest in statistical methods (and the ease with which a demand study can be used as the basis for a thesis). With both approaches, the past two decades have witnessed numerous empirical studies of specific commodities—and, more recently, of services—which have added considerably to knowledge of the effect of different variables on purchases, or sales. At the same time, this period has witnessed a growing emphasis on methodological improvements, and it is here that the principal developments in this area have taken place. For this reason, the present review is relatively brief and, in view of the orientation of this paper, focuses primarily on the use of household budget data.

In the area of demand analysis, considerable progress has been made in the specification and estimation of relationships. Recognition that price and possibly other relevant variables are not always independent of quantity led to more careful specification of demand relationships and to the development of more appropriate methods of estimation. Interdependence was taken into account by the equation-systems approach, using limited-information or reduced-form methods of estimation [e.g., 152]. For situations where the interdependence was not instantaneous, the simpler recursive method of estimation was developed and has been shown to yield highly effective results [170]. Although least squares is still probably the most widely used method of estimating the parameters of demand functions, in many instances justifiably so, and the controversy on the relative efficiency of the different estimation methods is by no means settled [e.g., 22], a wide variety of effective estimation procedures are currently available. (Perhaps the most recent innovation is the use of both income and total expenditures as instrumental variables in deriving Engel Curves [111A].)

Considerable progress has also been made in specifying the *ceteris paribus* of demand functions. A major innovation has been the introduction, and the significance revealed, of quality as a determining variable [15, pp. 36-46] [149, pp. 388-89]. Another innovation has been the attempt to allow discontinuity in reaction to changes in income and prices. One such attempt is exemplified by the "ratchet effect" of Modigliani and Duesenberry, according to which people continually adjust upward their living standards in response to peak standards attained in the past. A somewhat different approach has been that of Farrell, who

²⁸ For a brief description of these early studies, see G. J. Stigler [148].

allows for the possibility that demand relationships may be irreversible over time, that responses to a given change may depend not only on the amount of the change but also on the direction of change [39].

Further realism has been added through the use of lagged reactions, which have been shown to aid considerably in explaining fluctuations in demand [21, pp. 49-74] [151]. Distributed lags, and the so-called quasi-accelerator (in which demand is assumed to depend upon the rate of increase, as well as upon the prevailing level, of income), have also been introduced successfully in demand analysis [132].²⁹

Attempts have been made to derive demand functions not only for a single commodity at a time but for a large range of commodities. This technique has been used by the U. S. Department of Commerce as well as by Richard Stone in explaining fluctuations in consumer demand [137] [149]. Unfortunately, the use of a standardized equation for a wide range of commodities serves to place the demand function essentially in a statistical straitjacket, and at least one experimental study suggests that biased estimates of income elasticities may result [46, pp. 410-13].

Turning to the use of household-budget data, Engel's "Law"—that the proportion of household expenditure on food declines as household income rises—has by now been verified literally hundreds of times.³⁰ Generally, most studies also provide strong support for what is known as Schwabe's Law, namely, that the per cent of income spent for housing declines as income rises, although using permanent income concepts Margaret Reid alleges that high-quality housing in reality is one of the main luxuries of consumers [142] [144]. Further support for both laws was obtained in a study by Houthakker in which he derived Engel curves for 4 expenditure groups based on data from each of 40 surveys from 17 countries [73]. It is interesting that the function used in this study, as in many others, was essentially the same as used by Engel in his original paper, namely, a log-log relationship between the specific expenditure and total expenditures.

Recent studies reflect a growing interest in ascertaining the determinants not only of food expenditures but of a wide range of household purchases, such as housing, clothing, house furnishings, and services.³¹

²⁹ A general description of these and other innovations in demand analysis will be found in the recently published book by Robert Ferber and P. J. Verdoorn [49, Ch. 8, 9].

³⁰ For a partial list of studies, see the bibliography by James N. Morgan [127]. There has also been an abortive tendency to mangle the principle by refuting its applicability with time-series data, something that would make Engel turn over in his grave.

³¹ On clothing, see Dorothy S. Brady [13] and Morris Hamburg [68]; on house furnishings, see Vernon Lippitt [111]; on services, see Robert Ferber [47]; on housing see Sherman Maisel and Louis Winnick [116].

These studies show that these consumer purchases are influenced by a wide variety of socio-economic characteristics; but, nevertheless, the proportion of variance in individual household purchases explained by these numerous factors is small, often the order of .3 or less. In addition, these studies tend to bear out earlier findings on income elasticity, yielding low elasticities for food and housing, elasticities close to unity for clothing and education, and higher elasticities for various types of recreation, personal care, home operation, and other services.³²

Special attention has been given to the relationship between durable-goods expenditures, financial saving, and other variables; and strong evidence now exists that to a large extent purchase of durables is a substitute for financial saving [62A] [97] [118]. All of these studies find purchase of durable goods related to a variety of socio-economic characteristics, particularly age, income change, size of consumer unit, and various expectations. Studying the characteristics of a host of such purchases combined into "consumer investment" expenditures (purchases of cars, other durables, household equipment, and additions and repairs to houses), Morgan finds this category to have constituted a relatively constant proportion (between 12 and 16 per cent) of disposable income at all income levels, except the lowest and the highest, during each of the postwar years, 1947-56 [128].³³ Such expenditures are found to be influenced, as in other studies, by a variety of demographic and attitudinal variables, and are found to be sticky downward and flexible upward with respect to changes in income.

As in the area of demand analysis, linear (in some cases, logarithmic) single-equation forms have been used to derive from the same data marginal propensities and income elasticities for a wide range of consumption categories. This was the approach used by Prais and Houthakker on English data, and by Crockett and Friend on American data [32] [140]. The Friend-Crockett study analyzes by multiple regression analysis the effects on all major consumption categories of a large number of family characteristics including income. Among other things, their results indicate that family size and age, next to income, appear to exert the main influence on family consumption, particularly through the influence of family size on food expenditures and of age on durable goods purchases. The study also finds that income elasticities are reduced substantially once variables reflecting other family characteristics are introduced into the relationships.³⁴

³² For a summary of these earlier studies, see the review article by Ruth P. Mack [115].

³³ Morgan suggests that this proportion might have been constant at the highest income level too, if purchases of such items as summer homes, motor boats, and fur coats had been included.

³⁴ A basic question underlying many of these studies is whether they do provide

At the same time, dissatisfaction has been expressed over the rigid assumptions inherent in this approach. This dissatisfaction was crystallized to some extent by the findings of Prais and Houthakker that a semilogarithmic form is preferable for necessities and a log-log form is preferable for luxuries [140, pp. 87-103]; and by Stuvell and James that the use of only one form of equation to explain variations in food expenditures over the entire range of incomes and social classes is unsatisfactory [150].

One result of this dissatisfaction has been some interesting attempts to modify the Engel-curve approach. One approach has been to introduce nonlinearities into the expenditure-income relationship to allow for the possibility that a commodity may behave as a luxury in one range of income and as a necessity in a different range [139]. A Sigmoid response curve, which has an upper asymptote and at the same time passes through the origin, appears to yield realistic results in such instances [2].

Another approach, one that uses linear equations, has been to explain consumer purchases of specific goods on the basis of relationships between stocks and wealth rather than between income and expenditure. Quasi-Engel curves relating inventories to a measure of wealth have been derived by Cramer for a wide variety of household goods based on two Dutch surveys [29], and by Houthakker and Haldi for automobiles based on panel data for U. S. families [74]. The latter study is particularly interesting, showing that at a given level of income gross investment in automobiles varies inversely with beginning-of-the-year inventory, and that at a given level of beginning inventories, gross investment rises with income level.³⁵

Dissatisfaction with the linear-equation approach has also led to the use of variance analysis rather than multiple regression to ascertain the net effect of different variables on household expenditures. Variance analysis offers a more flexible approach to the estimation of relationships, since no assumption is necessary regarding the form of the functional relationship. As a result, studies using this technique do not

reasonably accurate estimates of the income effect on particular expenditures. To the extent that the permanent income hypothesis is correct, income effects estimated by relating current expenditures to current income can be understated substantially. Thus, in the case of housing, Margaret Reid obtains income elasticities of close to 2 by using average incomes for groups instead of data for individual households [144]. On the other hand, as noted earlier, Friend and Kravis obtained much the same income elasticities using 3-year averages of household income as from 1-year figures [59].

³⁵ It might be noted that a somewhat similar approach was used by Hans Brems on time-series data to predict the long-run equilibrium demand for automobiles based on a model relating stock of automobiles to the equilibrium rate of growth and the average age at which cars are scrapped [16]. An extension of this model, incorporating time lags, has been presented by Marc Nerlove [131].

always give the clear-cut simple results yielded by multiple regression, but in many ways appear to be more realistic, bringing out effects of various characteristics not only singly but in combination with each other (e.g., [31] [47] [111]). Unfortunately, as noted previously, several of these studies have utilized group averages rather than individual families as the unit of observation, thereby greatly reducing the chances of detecting interaction effects.

Another postwar development has been emphasis on obtaining and analyzing the expenditure and saving behavior of the same households over time. Popular for many years in marketing and advertising circles, the value of the consumer panel technique to economic analysis, and as a connecting link between time series aggregates and cross-section budget surveys, has only recently been recognized, stimulated in part by the emphasis of the permanent income hypothesis on the life history of the household. Panel studies undertaken so far have clearly demonstrated their value. In addition to studies discussed earlier [43] [87]³⁶ Houthakker and Haldi, in their automobile investment study, which was based on panel data, were able to isolate family taste as a separate variable. In another study based on panel data, Jean Crockett showed that income elasticities based on continuous panel data were much closer to time-series elasticities than the usual cross-section elasticities [31].

The introduction of panel data in budget studies highlights the growing interest in recent years in integrating the techniques of demand analysis and of household budget analysis. Time-series aggregates have serious disadvantages because of the frequently unstable estimates of income and of demand elasticities obtained as a result of the high correlation between income and prices. On the other hand, cross-section data are essentially static and are difficult to use as a basis for prediction. Hence, a combination of the two types of data would seem to offer a much more powerful technique for understanding consumer behavior.

Initial efforts made to integrate these two sets of data have been directed toward deriving independent estimates of income elasticities from budget data, inserting these estimates into an aggregate time-series demand relation, and estimating the parameters of the other variables from the time-series data [40] [153] [149, esp. Ch. 18]. An alternate approach has been to search for cross-section functions that might be expected to remain stable over time. This approach was used by Eleanor Snyder in a study finding a cross-section consumption relationship for food to yield essentially the same estimates of the parameters when applied to eight different cross-section studies between 1888

³⁶ Another study still being analyzed is a food purchase panel operated by Michigan State University. See G. G. Quackenbush [141].

and 1950 [147]. A more elaborate variation of this same general approach is the Crockett-Friend attempt to derive a complete set of consumer demand relationships [32]. Derivation of stable relationships of this sort could be used for prediction *if* distributional changes in these variables could be anticipated and *if* stability were assured.

This general approach has been carried one step further by Vernon Lippitt [111]. He applied analysis of variance to measure the effect of relevant cross-section variables on the particular item of expenditure. Estimates of the aggregate effects of these variables were derived for years for which the necessary cross-section data were available; estimates for intervening years were obtained by interpolation. These aggregate effects were then incorporated into a time-series function relating expenditures to these variables as well as to other pertinent time-series variables. Although details of the procedure may be questioned, and although this procedure still requires an independent estimate of distributional effects for predictive purposes, Lippitt demonstrates convincingly that this procedure is practicable and, in particular, that the distributional effect exerts a pronounced influence on estimated expenditures.

V. Household Decision-Making

The household can be viewed as a decision-making organization engaged in much the same activities as is a business firm. From this perspective, the household becomes a separate organization that receives income and other money receipts and that dispenses this money in accordance with certain criteria. Entering into these criteria are the wants and desires of different household members, the structure of the household and the interpersonal relationships existing among the different family members, all subject to various economic restraints. The explanation of consumer behavior then becomes a matter of identifying and measuring the relative importance of the factors that enter into the decision processes.

To borrow an analogy advanced by March and Simon in organization theory [117, pp. 178-82], the decision process can be subdivided into three distinct stages: (1) the manner in which the possibility of a particular action, e.g., purchase, comes to the attention of the household; (2) specification of, and deliberation among, alternative forms of action; and (3) the actual choice.

To illustrate, before a car is purchased, its desirability must first somehow come to the attention of the household. Then, different types of cars (brands, body-styles, etc.) as well as different forms (cash vs. borrowing) and times of making the purchase must be specified, however implicitly, and a certain amount of deliberation among these alter-

natives must take place. Finally, one alternative is selected as best and the decision is made to purchase (or not to purchase).

The usual consumer surveys and budget studies reflect the last stage of this process, namely, decisions in the form of actual purchases. Past empirical research on household behavior, as reviewed in the preceding sections, has been concerned with the measurement of these purchases and with the extent to which they appear to have been influenced by socio-economic characteristics of the household and, to a lesser extent, by its attitudes and expectations. In the latter sense, empirical research may be said to be reaching back into the second stage of the decision process. Nevertheless, from the point of view of decision theory, such results are of limited interest because no light is thrown on the dynamics of the decision process and, clearly, no knowledge is provided about decisions that were *not* consummated as purchases.

In recent years, an increasing amount of activity has focused on the second stage of the decision process, particularly on the extent of deliberation entering into consumer purchases. Thus, the previously cited works by Juster, Ferber, and Katona and his associates serve to reinforce the notion that many durable-goods purchases are planned and thought out carefully in advance. Particularly interesting in this respect is a study by Katona and Mueller on the extent of deliberation entering into purchase decisions of four major household durables (TV, refrigerator, washing machine, and stove) [89]. This study found considerable variation in the extent of advance deliberation among households. The actions of only about one-fourth of the group appeared to conform with the idea of the economic man, who considers a purchase very carefully and investigates numerous possibilities before making a final decision. An almost equal proportion were found to have made these purchases with virtually no advance deliberation, largely as a result of some fortuitous event. Extent of deliberation was more frequent among those with higher education, higher income, older people, and those in professional occupations, as well as among people expressing a liking for shopping. Deliberation was less frequent when the product was inexpensive relative to the buyer's income, when a special deal was offered, or when the product was needed urgently (as when the currently owned model broke down). Families under some financial stress did not appear to consider alternatives any more thoroughly than other families.

Attempts have also been made to explain the decision process in terms of accumulation of desires for and against making a particular purchase, based on the approach to social psychology of Kurt Lewin. This approach has been used by Warren Bilkey on consumer panels to obtain periodic measures from the same families of the psychic tensions

arising at various stages of the purchase decision. Intensity of desire for and against a particular purchase is measured in terms of positive and negative "valences" registered by the household; the more the excess of positive valences over negative valences, the closer is the decision to action [6] [7].

More recently, this theory has been extended into a general model of household buying-decisions by Joseph Clawson, who represents such decisions as the quantitative interplay of different motivations, status dimensions and intensities [24]. Except for isolated experiments, no general application has yet been made of such a model. Indeed, it remains to be shown that such an approach adds anything more to the explanation of the decision process than could be obtained from more straightforward data on buying intentions, attitudes and preferences.³⁷

Very little empirical work has been carried out on the attention-directing stage of the purchase process. This is not surprising in view of the more ephemeral nature of the problem. However, two interesting studies can be mentioned. One study, by Eva Mueller, attempts to ascertain the role of innovation in household purchases [129]. Among other things, it finds that innovators, defined as those who are among the first to purchase new types of appliances, are scattered throughout the population but, as a rule, are generally found among the young, among the well-educated, among married couples with children, and among those who are financially optimistic. People who already own similar appliances are more likely to be attracted to the new products, though this may reflect the interaction effect of assets and incomes.

The other study, carried out from a sociological point of view, traces how people through interpersonal contact become interested in purchasing air conditioners [168]. Based on block observations, this article shows rather strikingly how air conditioner purchases spread by means of neighborhood communication—among neighbors on the same block, over back alleys and over fences. The study suggests that this pattern of communication, particularly if catalyzed by the presence of a "leader," accounts for differences in ownership rates of air conditioners among blocks of the same socio-economic status. In addition, the study stresses the importance of the group in motivating people to purchase new products, inferring that "it is the group that determines when a luxury becomes a necessity" [168, p. 117].³⁸ Other sociological studies have also affirmed the importance of the group, and of leaders, in influencing purchase behavior [9] [91, pp. 234-47].

³⁷ The little work that has been done on the subject indicates that preferences may be very similar to purchase intentions, and that preferences are related to later purchases, at least as far as brand selection is concerned. See Seymour Banks [4].

³⁸ Much the same conclusion on the importance of community effects is reached by Dorothy Brady using an economic approach [10] [12].

VI. *Directions for Future Research*

The review of empirical work on decision processes of consumers in the preceding section is brief only partly because of the survey nature of this article. That empirical work in this area is only just beginning is highlighted by recent publication of a symposium volume on household decision-making which reflects in many ways a good picture of current thinking [54]. The bulk of this volume is devoted to exposition of theoretical approaches to various types of household decisions, ranging from changes in family composition and career choices to saving versus borrowing, and the allocation of expenditures. Empirical results, however, are meager and, with the exception of relationships between buying intentions and purchases presented by Juster, are largely inconclusive. As is evident from this volume, workable models of consumer purchase decisions have yet to be developed.

There is little doubt that empirical work in this area will be greatly expanded in the future, partly for its own sake and partly because of the stimulus provided by simulation and by game theory. Thus, before realistic simulation models of the consumer sector can be obtained, as is being attempted by Guy Orcutt and his associates at Wisconsin, knowledge must be available of the manner in which consumers make decisions and of the factors that enter into these decisions [134]. In a somewhat similar fashion, game theory has led to attempts to reduce consumer decisions to basic elements and to reproduce these decisions under laboratory conditions. Experimental work along this line by Wroe Alderson and his associates tends to support the feasibility of such an approach [3].

Among other things, this review serves to highlight the need for reconciling the different theories of the consumption function. In addition, much greater attention may be expected to the effect on spending and saving of the variables entering into the *ceteris paribus* assumption of the consumption function, particularly to nonlinear and irregular effects. Primary attention may be expected to be given to the role of assets, both their effect on the consumption function and as constituting a separate study area in itself. With asset ownership expanding tremendously year by year, even in recession, it would not be surprising to see a body of literature spring up on the study of "asset functions" to take its place alongside the study of the consumption function and the saving function.

Another area that can be expected to receive even more attention is the role of intentions, expectations, and attitudes on consumer behavior. In the past, these variables have been tested almost exclusively on their ability to predict durable goods purchases. However, there is no reason why modifications of these variables might not be equally

effective in predicting other types of purchases and even, as suggested by a recent exploratory study, in predicting saving [75].

The integration of cross-section with time-series data in explaining consumer demand is yet another area where significant advances can be expected in coming years. The means for such integration has been available for some time, namely, through the use of continuous consumer panels. By keeping continuous records, a comprehensive picture can be obtained not only of the factors influencing a household's purchasing and saving behavior but also of the manner in which decisions are made. Furthermore, this technique enables comparable cross-section distributions to be formed at different points of time and the joint distribution of these cross-sections to be studied over time. In addition, if the geographic scope of the panel operation coincides with an area that serves as a basis for aggregate statistics on incomes and expenditures, a basis is obtained for comparing and combining the data from these two very different sources.

Still another area where major expansion may be expected, and which has been the subject of relatively little empirical work in the past, is the study of the effect of household behavior on other sectors of the economy. The postwar experience has brought out rather dramatically that in a high-income economy consumers are no longer a passive force in business fluctuations, but constitute an autonomous force of their own. Thus, several of the recessions during the 1950's were mitigated considerably by the maintenance of consumer expenditures while activity in other sectors was turning down. Furthermore, the experience of more recent recessions suggests that one of the basic tenets of consumer behavior in the business cycle may be violated, namely, the positive relationship between the saving rate and economic activity. At least in a moderate recession, it appears that consumers may be treating various categories of expenditure rather than saving as residual variables [48]. Whether this is because of an overriding desire for security, or because debts accumulated during prosperity years are being paid off during recession, or for other reasons, remains to be established.

The final area in which much additional work can be expected is one which underlies all other areas of household behavior, and which should have received primary attention long ago, namely, the measurement problem. Consumer surveys and budget studies have multiplied enormously during the postwar period, both in this country and elsewhere.³⁹ These studies have been conducted in much the same manner as earlier ones and undoubtedly contain much the same errors.⁴⁰ These

³⁹ For a description of some of these studies see Jean M. Due [34]; also Eleanor Snyder [147], and the bibliography by James Morgan [127].

⁴⁰ A striking case in point is the new series of expenditure surveys of the U. S.

errors are not small. The few studies that have been made appear to indicate that, more than almost any type of economic statistics, data obtained from consumer surveys or budget studies are subject to substantial errors. As a rule, expenditures tend to be understated somewhat (some substantially, such as tobacco and liquor), income tends to be understated more, and saving tends to be understated most of all [107, pp. 113-50] [123, pp. 51-72]. Such errors are not uniform among different households or among population groups, though little basis exists for evaluation of their magnitude or effects; their influence on estimates of expenditures for population groups is essentially an unknown quantity. Above all, it is clear that past estimates of saving, whether obtained as a residual between income and expenditures or directly, are seriously in error, as are undoubtedly estimates of the distribution of assets and debts among the population [61].

Only one large-scale methodological study of data collection techniques has been undertaken in recent years, on means of improving the accuracy of savings data, under the sponsorship of the Inter-University Committee for Research on Consumer Behavior with financial assistance from the Ford Foundation and the U. S. Department of Agriculture. Initial publications of the study bring out clearly the substantial magnitude of the error problem, suggesting that biases in past surveys affect not only averages but distributions, and that the biases are large enough to render virtually meaningless the usual measures of sampling variation [108].

Under the circumstances, it is amazing how little attention is being given to the improvement of data collection techniques, and how much empirical analysis is focused on attempting to explain what may be no more than errors of observation.⁴¹ Occasional studies of different aspects of the problem have been made, principally by the Survey Research Center, the Federal Reserve Board, and other government agencies, but except for the project mentioned above, no concentrated effort has been made to deal with this problem or to develop new approaches to it. It is in the improvement of data collection techniques that perhaps the greatest strides of all are yet to be made. The sooner such strides are taken, the sooner a really firm basis will be reached for the analysis of household behavior.

Bureau of Labor Statistics. Originally, these surveys were to be preceded by methodological studies, but because of budget limitations these studies were eliminated although they had been begun. As a result, data are being collected in the same manner as in the past, and with the same unknown errors.

⁴¹ Thus, see comments by Margaret Reid [145]. Many of the findings of empirical studies reported at the *Conference on Consumption and Saving*, some of which were heatedly discussed, could have been due to errors of observation.

THE SOVIET PRICE SYSTEM

By MORRIS BORNSTEIN*

In the Soviet Union, as in all modern, complex economies, prices play an important part in the guidance of economic activity. However, their role in the Soviet economy is different both from their role in a capitalist market economy and from their role in a socialist market economy of the Lange-Taylor-Lerner type [50] [51]. In the Soviet economy (and in the Soviet-type economies of Eastern Europe and Communist China), prices are not an autonomous force determining production, resource allocation, and consumption. Instead, prices are manipulated by the central authorities as one of various instruments intended to accomplish their planned goals.

This paper is an analysis of the role of prices in the Soviet planned economy. Following a summary view of the various functions of prices in the Soviet economy, Sections I-III deal with three major subsystems of the Soviet price system: industrial wholesale prices, agricultural procurement prices, and retail prices.¹ In Section IV some general conclusions are presented. The operation of the Soviet economy (in regard to those aspects pertinent to the subject of this paper) may be characterized as follows:

1. The bill of goods is determined by a central authority, although in some cases in terms of categories, of varying breadth, the specific composition of which is determined by individual enterprises.

2. To secure this bill of goods, the central authority allocates resources primarily in physical terms, without the use of scarcity prices, by estimating production requirements on the basis of technological coefficients and by using physical balances to equate sources and uses of intermediate and final products.²

*The author, assistant professor of economics at the University of Michigan, is grateful to the Ford Foundation and the Joint Committee on Slavic Studies of the SSRC and ACLS for grants in support of research on which this paper is based.

¹Other parts of the price system, not analyzed in this paper, are wages, transportation rates, and foreign trade prices. On wages, see [12] [78]. On transportation rates, see [40, Ch. 11] [68, Ch. 6] [39]. Imports are sold within the USSR at internal ruble prices fixed on the basis of the prices of related domestic goods. On foreign trade prices, see [37] [16] [2] [77].

²On material balances and supply planning, see [54] [52].

3. The central authority specifies, ordinarily in physical terms but usually also in value terms, maximum inputs and minimum outputs for each enterprise, although enterprises may have some role in determining input and output mixes.

4. There is freedom of occupational choice, and money-wage differences constitute the principal mechanism for distributing the labor force.

5. Consumer choice exists, with households free to determine the distribution of their money incomes between consumption and saving and free to buy whatever goods and services they desire in view of prevailing prices and available quantities.³

6. As a result of the importance of economic growth in the political authority's preference scale, the central authority emphasizes investment at the expense of consumption, stresses maximum output rather than optimum utilization of resources, and not only fully commits but tends to overcommit the resources of the economy and of each enterprise.

Within this framework, the functions of the price system may be classified under three very broad headings: (1) control and evaluation, (2) allocation, and (3) income distribution.⁴

Control and Evaluation

Prices are used by the central planners to secure compliance by enterprise managers with the plans elaborated by the former and to evaluate the performance of the managers in the execution of their assigned tasks. Although resource allocation is determined by the planners largely in physical terms, it is necessary for them to express complex input and output targets for the enterprise in value terms in order to have a common denominator for physically dissimilar units of raw materials, labor, and capital goods. Thus the enterprise plan contains not only physical targets, but also value targets, such as those for value of output, cost, use of working capital, tax payments, and profits. To control and evaluate the use of inputs and the production of outputs by enterprises in physical terms alone would be extremely difficult, if not impossible. The use of value targets, moreover, enables the finan-

³ Some limited degree of consumer sovereignty also exists, to the extent to which the central authority responds to evidence, revealed by the exercise of consumer choice, that consumers would prefer a different output-mix from that allocated to consumption purposes by the central authority.

⁴ Various alternative classifications and groupings of the functions of prices in the Soviet (or Soviet-type) economy have been suggested, in Soviet and non-Soviet literature, including [6, pp. 93-95] [31, pp. 52-53] [60, p. 25] [55, p. 488] [45, pp. 25-27] [53, pp. 252-53] [48, pp. 22-23] [68, pp. 72-73]. On this aspect of the Soviet economy, as on many others, pioneering work was done by Naum Jasny [42].

cial authorities (the Ministry of Finance and the banking system) to participate in enforcing enterprise adherence to, and execution of, plan targets.⁵

For control and evaluation purposes, it is convenient to have prices which are stable over long periods of time and are based on the weighted average cost of the industry. The former facilitates intertemporal comparisons of output and cost, while the latter provides an "objective" standard with which the costs of a given enterprise may be compared.

Allocation

Because of the predominance of physical allocation, rather than allocation through the price system, the allocative function of prices is less important in the Soviet economy than the control and evaluation function. However, prices do influence the allocation of resources, and thus the pattern of production, in several ways. Four categories of participants in the economic process are involved: the central planning authorities, the managers of state enterprises, households in their capacity as suppliers of labor, and collective farms.

1. The Soviet planners (in *Gosplan*, the State Planning Committee, and in the planning organs of the ministries and regional economic councils) receive from the government (i.e., the leadership of the Communist Party) a number of broad targets, such as the size and distribution of the national product, as well as some specific targets, such as the level of military expenditures, foreign economic commitments, and physical targets for steel, coal, machine-tools, etc. The planners then deduce a pattern of output to attain these targets, primarily by the use of various "physical" tools, such as technical coefficients, material balances, and, more recently, some linear programming and input-output techniques [34, pp. 100-2]. Prices influence their decisions regarding the pattern of output and the allocation of resources only to a limited extent, in the following ways:

(a) Macroeconomic balances in value terms, such as national product and intersectoral accounts and capital-output ratios, are calculated and used to supplement, to a limited degree, the basic physical planning tools. To date, however, these value calculations appear to have been used primarily for an accounting function of measuring the results of physical planning decisions, rather than themselves serving as the basis for important production and resource allocation decisions [49,

⁵ Their role is strengthened by the Soviet policy of planning enterprise finances so that revenues exceed expenses by a narrow margin and by the requirement that enterprise funds be kept in the banking system, which supervises their expenditure.

p. 323] [15, p. 39] [1, p. 137].⁶ But Soviet planners appear to be moving toward a greater and more positive role for aggregate value planning, as a result of the advocacy of this approach by a number of prominent Soviet economists, the growing acceptance in the USSR of mathematical methods in economics, and the progress of Soviet computer technology.

(b) Prices may have some influence on the selection of technological coefficients for physical planning. Certainly, there are alternative production functions for many goods, and in the course of successive iterations in the balancing process, the technological matrix may be adjusted through the substitution of more abundant for scarcer materials. It has been suggested that relative pricing of substitutes, especially those involving "deficit" commodities is intended to guide the planners at least as much as the managers of state enterprises [31, pp. 60-61]. To the extent to which this occurs, higher relative prices direct scarcer commodities to "more important" uses (i.e., those outputs higher on the planners' priority scale, which are not necessarily those outputs which themselves have higher relative prices).

(c) The planners (including here the "project makers" or design engineers) make allocation decisions involving value calculations. These include decisions regarding alternative variants of a given-output investment project and the assessment of the benefits of modernization or innovation. Both of these involve a choice among alternatives on the basis of a value comparison of heterogeneous inputs (and the latter of outputs as well) and of the present and the future [44] [32] [24].

2. Prices also perform a limited allocative function at the enterprise level, because managers exercise a narrow range of choice and are guided in these choices by prices. It is impossible for the central authorities to specify in complete detail the inputs and outputs of each enterprise. The central authorities usually specify output targets in aggregate (or only slightly disaggregated) physical and value terms—for example, the principal categories of output in tons and the total value of output in rubles—giving the enterprise manager the responsibility to select the types, models, qualities, sizes, etc. Likewise in regard to inputs, the manager is told the amounts of the principal materials, the equipment, and the number of workers in each labor classification that he is authorized to use to achieve (and, if possible, surpass) his plan

⁶ Foreign-trade planning is an important exception requiring some value planning. Even if trade is not based on a comparison of domestic and foreign price ratios, value comparisons in foreign currencies are needed for balance-of-payments reasons. Thus, foreign-trade planning may be done in physical terms (by material balances and technological coefficients) subject to a specified balance-of-payments constraint.

targets. Within these limits, the manager exercises discretion in deciding how to use the resources at his disposal to fulfill the enterprise plan, or, if it cannot be fulfilled in all respects, which parts to fulfill at the expense of which others [13, p. 20] [59, pp. 1-2]. The pertinent prices influence his decisions regarding alternative outputs and inputs.

3. In the Soviet economy, prices affect both the total supply of labor and its distribution. Participation in the labor force is not compulsory. Rather, the state relies on low real wages, resulting from the relationship of money wages and consumer prices, to evoke a high participation rate.⁷ Wage differences, in turn, are the principal means of securing the distribution of the labor force (by skill, industry, enterprise, and geographical location) which the planners desire.⁸ The wage structure is not a guide to the planners in their decisions regarding resource allocation, but rather an instrument for executing these decisions, i.e., for securing the allocation of labor planned in physical terms. Yet the wage structure allocates labor in the narrow sense that relative prices, rather than physical commands, are used to direct labor to the places assigned in the plan.

4. In the collective farm sector, the central authorities have used prices, along with delivery quotas, to influence the allocation of resources to certain crops and products in preference to others.⁹

To perform these allocation functions, scarcity prices, not merely accounting prices, are required. Only scarcity prices will lead planners to allocate resources efficiently and encourage enterprise and collective farm managers to produce the "best" (according to planners' preferences) assortment of goods in the most economical manner. Likewise, because wages are supposed to equate labor supply (by households) and demand (of enterprises, according to planners' targets), they also should be scarcity prices.

Income Distribution

In the Soviet economy, the basis of income distribution is the "socialist" principle of unequal monetary compensation according to labor services rendered, rather than the "communist" principle of distribution

⁷ Participation rates are discussed in [23, pp. 78-81].

⁸ At the present time, qualifications to this simplified statement include (1) forced labor, (2) determination of the skills of the labor force through control of the educational system, (3) assignment of new graduates of technical schools and universities to their first jobs, and (4) such restrictions on mobility as the housing shortage. However, the much more stringent restrictions on freedom of occupational choice of the Stalin era have been eliminated [28] [17] [7].

⁹ In addition, prices have been used (along with delivery quotas) to stimulate total output, but the aim in this case has been primarily to increase the productivity of given resources engaged in agriculture, by increasing real compensation and thus incentives.

according to need; and the promise of unequal monetary compensation is the basis of production incentives.¹⁰

The price system thus determines in the first instance the distribution of money income. The distribution of real income, in turn, is achieved primarily by the sale of goods and services to households exercising free choice in the expenditure of their (unequal) money incomes.¹¹ However, in an effort to make the distribution of real income less unequal than the distribution of money income, the Soviet government fixes low prices for mass consumption goods and high prices for luxury goods by means of differentiated turnover taxes.¹²

Prices thus are called upon to perform several important functions in the Soviet economy. The remainder of this paper is devoted to an appraisal of how well Soviet prices perform their assigned tasks. For this purpose, the Soviet price system is divided into several distinguished interrelated subsystems: industrial wholesale prices, agricultural procurement prices, and retail prices.

I. Industrial Wholesale Prices

The term industrial wholesale prices is here applied to the prices at which goods are transferred or evaluated within the state sector of the Soviet economy. The term covers prices of producers' goods, including raw materials, semifabricates, and machinery, as well as manufactured goods. It excludes prices at which agricultural products are bought by the state from collective farms but includes prices at which government agencies sell agricultural products to state enterprises for processing or to trade organizations for retail sale without further processing. It also excludes foreign trade prices, although it includes prices at which foreign trade organizations buy from and sell to state enterprises.

Types of Industrial Wholesale Prices

The following are the principal types of Soviet industrial wholesale prices [48, pp. 110-11] [53, pp. 93-94] [60, pp. 262-63] [18, p. 53]:

¹⁰ For wage-earners paid on a piece-rate basis, and for managers motivated by the desire for money bonuses [13, Ch. 3-4], the additional money income from more output (and, to a lesser extent, cost-savings, above-plan profits, etc.) means more claims to consumer goods. In the case of the collective farm sector, it is the relationship between (a) state (and free-market) prices for agricultural products and (b) state prices for agricultural inputs and consumer goods bought by collective farmers, that determines the "terms of trade" and the incentive to produce.

¹¹ During "War Communism" (1917-21), payment in kind was widely used [8, p. 43], and during the early 1930's and the Second World War a unique form of differential physical rationing was employed [8, pp. 233-50] [72, pp. 73-74].

¹² The distribution of real income is also less unequal than the distribution of money income because of (1) the allocation of housing and (2) the informal rationing of queues and empty shelves when retail prices are fixed below the market-clearing level.

1. *Enterprise wholesale price (optovaia tsena predpriatia)*. This is the price at which a producing enterprise sells its product to other state enterprises. It excludes turnover tax on the product but includes any turnover tax previously paid by the enterprise on materials going into the product. If the enterprise is responsible for delivery of the product, this price covers transportation cost.

2. *Industry wholesale price (optovaia tsena promyshlennosti)*. This is the price paid by the state-enterprise buyer and includes, in addition to the enterprise wholesale price, the following: (a) the turnover tax, if any, on the product; (b) the mark-up of the industry sales organization, if the product is sold by a central sales organization rather than by the individual enterprise itself;¹³ and (c) transportation charges, if these are borne by the sales organization rather than the buyer. If there are no turnover taxes on the product and the product is sold by the enterprise itself, rather than by a central sales organization, the enterprise wholesale price is also the industry wholesale price.

3. *Settlement price (raschetnaia tsena)*.¹⁴ In some industries where production costs diverge widely, notably in petroleum extraction, individual enterprises or groups of enterprises receive different prices, rather than a single, uniform enterprise wholesale price. In this case, the industry sales organization buys from the enterprise at the individual settlement price and sells to customers at the industry price.

4. *Price of "own procurement" (tsena sobstvennovo zakupka)* is the price paid by enterprises, especially small state enterprises of a (*raion*) subordination and producers' cooperatives, for scrap and raw materials, particularly construction materials, obtained from collective farms.

5. *Local wholesale price (mestnaia optovaia tsena)*. This is the price at which a product made from "own procurements" of raw materials is sold by such enterprises.

Of these five categories of prices, the first three are the most important, applying to the overwhelming bulk of Soviet industrial production, and are fixed by the national or regional authorities. The last two, of lesser importance, are fixed by the local authorities.

Functions of Industrial Wholesale Prices

Three principal functions of Soviet industrial wholesale prices may be distinguished: (1) assistance to the planners in the elaboration of

¹³ For example, the centralized sales scheme is used in the metallurgical, petroleum, and cement industries, while chemical and machine-building enterprises sell their products themselves [48, p. 110].

¹⁴ Also translated sometimes as "accounting price."

a plan, (2) guidance for managerial choice among inputs and outputs, and (3) control and evaluation of managerial performance.

1. Soviet planners calculate many value aggregates, including those of output, cost, wages, sales, and the national accounts. Industrial wholesale prices, along with agricultural procurement, retail, and foreign-trade prices, are necessarily used in these calculations. For example, enterprise wholesale prices are used to calculate value of output and labor productivity targets for individual enterprises and groups of enterprises. Industry wholesale prices—at which goods are transferred within the state sector—are used in the calculation of costs, sales value, profits, and the contribution of the industrial sector to the national product. Both current and constant prices are used, depending on the purpose of the calculation. Industry wholesale prices, together with planned wage rates and transportation charges, are used in the derivation of “estimate prices” (*smetnye tseny*), at which construction cost estimates are prepared [53, pp. 209-13].

As a rule, industrial wholesale prices are used by the planners without any adjustment.¹⁵ However, there is an exception in the case of investment-project planners, whose task is to choose among alternative technological variants of a given-output project (e.g., a thermal or hydro-electric power station of a given capacity). In comparing operating costs against initial construction costs, they have sometimes used various “coefficients of scarcity” (*koeffitsienty deficitnosti*) to correct what they regarded as unduly low industry wholesale prices, which, in their opinion, inadequately reflected the scarcity of various raw materials. Because little has been published regarding these adjustments,¹⁶ it is not possible to estimate how widely they are used or how great are the adjustments made to the established industry wholesale prices. In the absence of information on these questions, it is assumed in this paper that the planners in general use the established industrial wholesale prices.

Although industrial wholesale prices are indispensable in the elaboration of output, cost, sales, and profit targets, these value calculations fill primarily an accounting function rather than serving as the basis for allocation decisions.

2. The allocative effect of industrial wholesale prices is felt primarily in the guidance of managerial choice among alternative outputs and inputs. The enterprise plan specifies total output and its main component categories (the “assortment plan”), but the enterprise manager usually exercises some choice regarding the detailed composition of these categories, i.e., the types, grades, sizes, and qualities. He also has

This is the case also in the construction of the national accounts.

The most extended discussion which I have been able to locate is [47, pp. 49-50].

some discretion regarding his input-mix for a given output, although this discretion is sharply limited both by the technical possibilities for altering his production functions and by the physical allocation of many materials and the earmarking of expense categories by the central authorities.

In regard to outputs, the structure of industrial wholesale prices is supposed to induce managers to fulfill the assortment plan, in the first instance, and, within the limits of the assortment plan to stress scarcer in preference to less scarce items and higher quality in preference to lower quality items [53, pp. 131-32]. Similarly, in regard to inputs, the structure of wholesale prices (and freight rates) is supposed (1) to encourage the use of less scarce in preference to scarcer varieties of materials (e.g., ferrous rather than nonferrous metals); (2) to economize transportation by making local materials and fuels "cheaper" to users than materials and fuels from distant sources; (3) to carry out a given fuel balance policy (favoring the use of coal and natural gas, in preference to petroleum); and (4) to promote mechanization, by encouraging the use of larger rather than smaller machines and the adoption of new models [53, pp. 118-21].

3. Finally, in the control and evaluation of managerial performance, industrial wholesale prices are used (along with other prices, such as wage rates, transportation rates, and, in the case of retail trade enterprises, state retail prices) in measuring the degree of fulfillment of plan targets. They are similarly used in comparing the performance of the enterprise, in regard to output, cost, and profit, with the performance of other enterprises and with its own performance in earlier accounting periods.

"Good" or "successful" managerial performance is nominally measured in terms of the degree of fulfillment of the enterprise plan, but the latter, in turn, is composed of a number of targets or indicators, including those for output, cost, and profit. However, the structure of rewards for good, and penalties for bad, managerial performance specified by the central authority establishes a clear hierarchy in which the "quantitative" total output target ranks above such "qualitative" targets as those for the composition of output (the "assortment plan"), profit, and unit cost [13, p. 71] [29, pp. 271 ff.]. In making such choices as are available to him in his circumscribed area of decision-making, the enterprise manager endeavors to achieve those plan targets which are accorded more importance in the evaluation of his performance by higher echelons, at the expense of those regarded by them as less important.¹⁷

¹⁷ For example, the assortment plan may be sacrificed in favor of the gross value of output plan by producing more of the higher-priced and less of the lower-priced items

This distinction is significant in the analysis of Soviet industrial prices because output (total and assortment) may be measured in different (relative) prices than cost and profit. (Output is also often measured in physical units.) Output is evaluated at constant enterprise wholesale index prices of some base period or date, because intertemporal comparison of the growth of output is of prime interest. Cost and profit are measured in current prices at which goods are transferred, including materials costs at industry wholesale prices and sales revenue at enterprise wholesale prices. These constant prices may be identical to current transfer prices at some point in time, such as the beginning of a long-term plan period, but they tend to diverge in level and structure as the two evolve separately.¹⁸

Output targets and input authorizations are also specified in physical terms, such as linear meters of cloth, tons of weight, surface area, etc. These give rise to what Grossman has called physical quasi-prices [31, p. 54], measuring the terms of exchange between alternative products either in fulfilling the output target, or as input costs. Clearly, the relative importance of different products as measured in these physical units is likely to differ from their relative importance as measured by their relative prices either in the constant index price structure or in the current transfer price structure. Thus, a third price structure may be distinguished.

Because different enterprise plan targets or authorizations are specified in different prices, the relative importance of the different kinds of prices depends on the relative importance of the targets expressed in them. Because output targets are of primary importance, constant index money prices and physical quasi-prices tend to influence managerial decisions more than current transfer prices. As between the first two types of prices, both of which may be used in the measurement of out-

in the enterprise's production schedule. Likewise, the relatively more material-intensive items may be produced at the expense of the less material-intensive, since the former contribute more, for a given amount of labor involved in their processing, to the final value of output. Similarly, the assortment plan may be sacrificed in favor of the profit plan by producing more of the items with higher unit profits and less of those with lower unit profits. Targets for cost reduction may be met not by increasing efficiency in the use of inputs but by decreasing quality [59] [48, pp. 32-33] [13, pp. 117-19]. To enforce closer adherence to the assortment plan limited experiments have been undertaken to measure value of output on a value-added (i.e., wages or wages and profits) basis, rather than in terms of gross value of output [25]. Also bonuses for fulfillment and overfulfillment of output plans have been made contingent, at least in some industries, on the fulfillment of cost reduction plans [61].

¹⁸ This divergence may be substantial, as during the 25-year period that 1926/27 prices were used for output calculations despite many changes in current transfer prices [57], or relatively modest, as during the period beginning in 1956 during which transfer prices of July 1, 1955 have been used as constant prices for output calculations and there has been no general change in transfer prices.

put, their relative importance differs from industry to industry, depending upon the extent to which total output targets may conveniently be expressed in physical units.

Formation of Industrial Wholesale Prices

Soviet enterprise wholesale prices are composed of two principal parts: planned average branch cost of production (*sebestoimost'*) and a profit mark-up.

The Soviet cost concept of *sebestoimost'* has no exact equivalent in Western cost accounting. It includes direct and indirect labor, including wages, salaries, and social insurance payments; basic and auxiliary materials, including fuel and power; depreciation (but not depletion) allowances; and various overhead expenses, such as those for postage, business travel, and expenditures for workers' housing and for workers' education.¹⁹

Although in some instances differential rent and short-term interest payments for working capital are included in *sebestoimost'*, both rent and interest on capital are ordinarily omitted. As a result, Soviet cost accounting practices, in comparison with the results that would be obtained if Western accounting practices were used, result in lower total nominal costs and in different relative costs as among products and industries [69, p. 143].²⁰ For convenience, *sebestoimost'* is hereafter rendered in this paper as "cost of production" or "production cost."

The cost figure used as a basis for enterprise wholesale prices (and, in turn, industry wholesale prices) is the planned average cost of production of the enterprises producing the product. However, the figure is not simply a weighted average of planned costs of all producers, but, rather, excludes some of the highest cost producers. The Soviet literature on the subject reveals some dispute about how "progressive" (i.e., how ambitious) the cost target should be. Some writers advocate a cost target based on the performance of "leading" enterprises [53, p. 103], while others favor a more modest target which takes into account the capabilities of all enterprises in the corresponding branch of industry [48, p. 108].

The other component of enterprise wholesale prices, in addition to planned average branch production cost, is a profit mark-up intended to

¹⁹ There are several slightly different concepts of *sebestoimost'*, corresponding to the differences between gross and net production and shop and enterprise expenses [53, pp. 95 ff.].

²⁰ The shares of the principal components of the *sebestoimost'* for aggregate Soviet industrial production in 1959 were as follows (in per cent): basic materials, 63.9; auxiliary materials, 4.8; fuel, 3.6; power, 1.7; labor, 19.3; and others, 3.2 [67, p. 161]. The deficiencies of Soviet cost accounting are analyzed in [19].

provide a "normal" profit, for the branch as a whole, of about 5 per cent [5, p. 290] [48, p. 84] [68, p. 13]. Profit in the Soviet economy is not intended to allocate resources among alternative uses, but rather to provide a source of net income or accumulation to the state, to serve as an instrument of financial control, and to promote the "business-like" operation of Soviet enterprises.

A major part of the profits of Soviet enterprises is paid to the state budget as profits tax, while the remainder is retained by the enterprise for the expansion of its fixed and working capital and for the payment of bonuses and the construction of housing, nurseries, and recreational facilities for the workers of the enterprise. In addition to the use of its retained profits, the enterprise's expansion may be financed through budget grants representing the redistribution of profits tax and other tax collections. Periodic payments of profits tax liabilities, based on planned profits (which are in turn based on planned sales and costs), furnish a basis for supervision and control of enterprise operations by the financial authorities.

For both the accumulation and control purposes, the turnover tax also can be, and is, used. Soviet writers stress that profits and the turnover tax are both forms of "net income" (*chisty dokhod*) to the state, and that both are needed, since each has its own special function. That is, although their economic nature—as a vehicle for monetary accumulation—is the same, they perform different roles in economic organization and administration. Profit is considered a tool of control designed to measure (one facet of) managerial performance. But it is convenient to have a supplementary form of accumulation which provides net income to the state without at the same time constituting enterprise income. Thus, in the case of consumer goods production, a high rate of accumulation can be achieved through the turnover tax without involving an abnormally high rate of profit for producing or trading enterprises [3, pp. 158-60] [5, p. 293].

Underlying this conception of the nature and role of profit is the notion that efficient operation of enterprises is promoted by a rather modest level of profit and is discouraged by either above-normal profits or below-normal profits or planned losses. It is asserted that unduly high profits fail to spur managers to reduce costs. Likewise planned losses and subsidies discourage managers from striving for lower costs and lead them to depend on outside assistance in the form of budget grants, rather than to maintain the financial independence that goes with "sound" operation. On the other hand, a pricing policy that keeps most enterprises in the industry near the margin of profitability is believed to promote efficiency, at the same time that it provides, through profits

tax liabilities, a vehicle for control over enterprise operations by the financial authorities [68, pp. 80-81] [48, p. 82].²¹

There are two principal reasons why enterprise wholesale prices have in various cases exceeded the level necessary to cover cost and provide a small profit. One arises simply from the infrequency with which prices are revised. The last general revision of industrial wholesale prices occurred on July 1, 1955, and the preceding one on January 1, 1952. The next revision is apparently scheduled for 1962 [63, July 17, 1960]. During the interval between price revisions, reductions in costs lead to profits much in excess of 5 per cent in industries, such as machine-building, characterized by rapid changes in productivity. Second, above-average profits occur in the case of "deficit" or scarce commodities which are assigned relatively high prices, compared to the prices of substitutes, to discourage their use. However, this use of industrial wholesale prices as an allocation device—i.e., as a partial rationer of commodities—has been confined to a comparatively small number of basic industrial goods, notably nonferrous metals such as copper, tin, and lead, quality steels, and refined petroleum products [69, p. 158].

Much of the Soviet literature on price formation is concerned with the conflict arising between the belief that a "normal" profit promotes efficiency and the fact that average-cost pricing inevitably means above-normal profits for lower-than-average-cost producers and below-normal profits (or losses) for higher-than-average-cost producers. Wide variations in unit costs of production exist, for example, in the extractive, metallurgical, machine-building, textile, footwear, and sugar-refining industries, due to differences in natural conditions of production, distance from sources of raw materials and fuels, technology, degree of specialization of production, and regional wage rates [68, pp. 74-75]. To cope with the resulting differences in costs, two main approaches are used. In the metallurgical, chemical, and light industries, uniform enterprise wholesale prices are widely used, and the resulting variation in profitability, ranging from planned losses to high profits, is met through intradepartmental redistributions of funds to the enterprises in the former category from those in the latter.²² On the other hand,

²¹ In Soviet parlance, this is the pricing policy which is consistent with *khozraschet* ("business calculation") operation of enterprises, the characteristics of which are (1) the exchange of goods on the basis of state supply plans and contracts; (2) covering all of the enterprise's current (i.e., noncapital) expenditures from its own revenues; (3) direct dependence of the financial status of the enterprise on the effective use of its resources, i.e., on the successful fulfillment of the various targets of the enterprise plan; (4) control of enterprise activity through the control of its financial resources by budget and credit controls; (5) "material self-interest" of the employees of the enterprise in its financial results; and (6) personal and individual responsibility of the enterprise director for the use of state resources in accordance with the plan [53, pp. 58-59].

²² Under the functional form of economic organization in effect up to mid-1957, these

some industries use settlement prices, which are different for each enterprise (as in sugar-refining) or group of enterprises (as in petroleum extraction) [68, pp. 82-84].

In both cases, however, the objective is to secure a single buying price for buyers of the product, in order to make their costs (in regard to raw materials and fuels), and thus their performance, more comparable. The widespread use of delivered prices (in some cases, differentiated according to geographical zones) is also directed toward this end. In addition, it places the demand for transport services with the seller, who is likely, under the prevailing conditions of a "sellers' market," to be less wasteful of them than the buyer [31, p. 61].²³

The industry wholesale price for a good may differ from the enterprise wholesale price because of the turnover tax, as well as because of the sales mark-up and transportation charges. Before the 1949 price reform, the turnover tax was levied at very low rates (usually .5-1 per cent) on various producer goods to give the financial authorities an additional instrument of supervision and control. Since the 1949 reform, it has not been levied on producer goods except in the case of petroleum products, natural gas, and electric power, where the tax (rather than a higher profit mark-up) is used to secure the desired relative price structure for alternative sources of energy—i.e., to raise the prices of these sources relative to the price of coal [68, p. 24].

On the other hand, in the case of some manufactured consumer goods, such as textiles, the turnover tax has been levied since 1939, and particularly since 1949, in a way intended to use the enterprise wholesale price structure to promote the fulfillment of the enterprise's assortment plan. On most manufactured consumer goods, the tax is levied as a specific ruble amount, permitting the existence of two distinct price structures—one for the state retail prices at which these goods are finally sold to households and the other for the enterprise wholesale prices received by producers. The difference between the two prices consists of turnover tax and mark-ups for the industry's central sales organization and for the wholesale and retail trade network. Thus the relative prices of two goods in the state retail price

involved redistribution of profits within a ministry. Under the territorial form in effect since then, funds are transferred among enterprises within a regional economic council [68, pp. 79-81].

²³ The delivered price charged by a central sales organization is usually FOB station of destination and covers the enterprise wholesale price, central sales mark-up, and average transportation cost. FOB station of origin is commonly the basis of price quotation when there is no central sales organization, or when transportation charges are not large relative to the price of the good, as in the case of machinery. Zone pricing is used when transportation charges are large relative to price (e.g., in the case of construction materials) in an effort to prevent excessive absorption of transport costs and excessively long hauls [53, pp. 139-44] [68, pp. 91-99].

structure need not be, and usually are not, the same as their relative prices in the enterprise wholesale price structure. In the former, relative prices are set to manipulate consumption—essentially to adjust sales to supply. In the latter, prices are set with the aim of providing equal profitability for alternative varieties of output and thereby eliminating the incentive to achieve the gross value of output target by “violating” the assortment plan. If the tax were levied not as a specific ruble amount but as a uniform percentage of the final retail or wholesale price, the effect would be to apply the state retail relative price structure to the output of the producing enterprise. Under this price structure, certain varieties of output would be more profitable to produce than others, and the enterprise would attempt to produce more of the more profitable varieties and less of the less profitable varieties than called for in its assortment plan, since by doing so it would have to use less rubles of inputs to produce a given 100 rubles of output [48, pp. 121-31] [68, pp. 330-34].²⁴

Evaluation of Industrial Wholesale Prices

Soviet industrial wholesale prices clearly are not scarcity prices, inasmuch as they are fixed on the basis of average labor costs and neglect scarcity and demand. Supply and demand relationships are largely ignored in price determination (again, with some exceptions), and surpluses and shortages rarely lead to changes in these prices. How satisfactory are such prices for the performance of the three functions distinguished above?

1. Such accounting prices clearly do not offer sound guidance to the planning authorities in the choice among alternatives regarding production and investment, since they do not accurately measure the marginal costs of alternative inputs or the marginal values of alternative outputs. By omitting land and capital charges, these prices lead to the undervaluation of raw materials and equipment relative to labor in cost calculations and to the excessive use of the former relative to the latter. Recognition of these defects of industrial wholesale prices [48, p. 37] [65, p. 35] no doubt explains in part the unwillingness of Soviet planners to use them as the basis for resource allocation decisions and their reliance, instead, on physical planning techniques. Yet the preference for physical planning and the suspicion of prices as a proper device for socialist resource allocation have surely contributed to the Soviet

²⁴ The tax is still levied as a percentage of the retail price in the case of many goods, particularly those whose assortment is considered relatively narrow (such as light bulbs, radios, and clocks) on the ground that in these cases the administrative advantage of not having to fix individual turnover tax amounts outweighs the disadvantage arising from the enterprise's incentive to deviate from the assortment plan [53, pp. 82-83].

failure to devise industrial wholesale prices which would more closely reflect scarcity.

The consequence of the reliance on physical planning, however, is that the resulting plans are not based on the precise evaluation of the terms on which alternatives are offered which a system of scarcity prices would provide. Hence, the plans do not achieve the optimum use of resources for the attainment of the goals set. (Also, the regime itself does not know with comparable precision the opportunity costs of alternative decisions facing it.) However, in the absence of scarcity prices, there may well be no loss, and indeed there may be some gain, in rationality by using physical planning techniques in preference to value calculations involving nonscarcity prices. Given the present industrial wholesale prices, Soviet planners may be wise not to rely on value planning.

2. Because Soviet industrial wholesale prices do not reflect relative scarcities of goods and factors of production, they likewise are not desirable guides for the choices among alternative inputs and outputs which enterprise managers are authorized to make (or which they make without authorization in the course of achieving some plan targets at the expense of others). However, precisely because the central authorities lack confidence that industrial wholesale prices will lead enterprises to achieve the results they desire of them, they limit severely, by commands and directives in physical terms, the range of choices which enterprise managers can make on the basis of these prices.

3. The principal function of industrial wholesale prices is the control and evaluation of enterprise performance in the fulfillment of plans determined by the central authorities principally through physical planning. For this purpose, prices of the (merely) accounting type are satisfactory, and the lack of scarcity prices is not necessarily disadvantageous. Accounting prices do provide a supplementary method of verifying adherence to physical plans, and average-cost pricing facilitates comparison of the performance of the individual enterprise with that of the industry as a whole. The absence of an interest charge on fixed capital, although a serious deficiency in so far as allocation of capital is concerned, is not important for the control and evaluation of the enterprise, because capital as such (as distinct from specific capital goods) is not among the inputs which are entrusted to the manager and whose use by him in accordance with the enterprise plan is to be enforced and evaluated with the aid of the price system. Thus, although they fail to reflect relative scarcities, industrial wholesale prices can nevertheless perform their control and evaluation function reasonably well.

The unsuitability of industrial wholesale prices for allocative purposes restrains any inclination on the part of planners to shift toward value, rather than physical, planning. It also is a barrier to any substantial decentralization of decision-making to the enterprise level under which enterprise managers would determine their inputs and outputs on the basis of value calculations of cost, revenue, and profit. Either or both of these changes in Soviet economic planning would require a system of scarcity prices, reflecting both supply and demand (according to planners' preferences), upon which the central authorities could rely to secure the resource allocation and bill of goods which they desire.

II. *Agricultural Procurement Prices*

Agricultural procurement prices here refer to the prices at which agricultural producers sell to state procurement agencies. Collective farm market prices, at which agricultural producers sell to households, are analyzed in the following section as retail prices. Most of the discussion in this section concerns the agricultural procurement prices paid to collective farms, since the prices paid to state farms are essentially similar to the industrial wholesale prices analyzed in the preceding section.²⁵

State Farm Procurement Prices

State farm delivery prices (*sdatochnye tseny sovkhovov*) are essentially different in nature from the agricultural procurement prices paid to collective farms. In the case of state farms, the delivery price is a "transfer" price which performs only a nominal "accounting" function. In the case of collective farms, agricultural procurement prices directly and strongly influence the volume and composition of output.

State farms are "factories in the field" with a *khozraschet* status (see fn. 21) similar to that of state enterprises in industry, transportation, etc. Their employees receive money wages on a piece-rate basis, and they calculate cost of production (*sebestoimost'*) in essentially the same way as other state enterprises. Accordingly, their delivery prices are supposed to be comparable to enterprise wholesale prices in in-

²⁵ This analysis of agricultural procurement prices draws heavily on the comprehensive studies of Nimitz [56] and Karcz [46], to which the reader is referred for a more detailed discussion, supported by extensive statistical data. The latter also contains a discussion of various other, minor aspects of the pricing of agricultural products, such as the valuation of payments in kind by collective farms to the former machine tractor stations (MTS's), and "return sales" whereby, in addition to money payments, producers of selected crops received preferential opportunities to buy specified agricultural and industrial products at privileged prices. Return sales are also discussed at length in [68, pp. 277-83].

dustry, covering cost of production (as reckoned in Soviet state enterprises) plus a small profit mark-up. Like other state enterprises, they are subject to profits taxes, on the one hand, and are entitled to receive budget grants, normally only for the expansion of fixed and working capital, on the other.

In practice, however, state farm delivery prices have usually been fixed very close to the corresponding state purchase prices for collective farms. These prices have not been high enough to cover state farm operating costs, and as a result state farms have long shown large operating losses (both "planned" and "unplanned") which were met by operating subsidies from the budget [48, pp. 81-82]. Thus, the pricing of state farm deliveries has not in fact followed the operating-cost-plus-profit criterion generally applied since 1949 to industrial wholesale prices. Apparently the Soviet government has been reluctant to fix state farm prices "out of line" with collective farm prices. Since state farm costs (and thus, prices) are supposed to serve as a model and target for collective farms, state farm prices could hardly be fixed above the prevailing collective farm procurement prices!

Because state farm costs are reimbursed by the combination of delivery prices and subsidies, the failure of prices to cover costs does not restrain output. In contrast, in the case of collective farms, which do not receive subsidies, prices are the sole source of compensation for production expenses and productive effort. Because collective farmers do not receive fixed money wages but are instead residual claimants to the net income of the collective farms (after precedent claims for material production expenses, taxes, investment, etc., have been satisfied), the level of procurement prices has a direct effect upon their incentives and thus their productivity and output.²⁶

Collective Farm Procurement Prices

1. *Objectives.* In setting agricultural procurement prices for collective farms, the Soviet government has pursued two conflicting objectives: (1) to fix the terms of trade for the collective farm peasantry so as to make it bear a large share of the burden of industrialization, and (2) to provide incentives to produce.

In the first case, the state has determined the terms of trade and real income of the peasantry through the relationship between agricultural procurement prices paid to the collective farms, on the one hand, and prices paid by the collective farms for material inputs and prices paid

²⁶ Since 1958 a small minority of collective farms has shifted to a wage basis, that is, full monthly payments at fixed rates for specific tasks or norms of production [56, p. 275]. Even under these circumstances, the level of procurement prices determines the level of wages which can be paid.

by collective farmers for consumer goods, on the other.²⁷ Because the collective farm peasantry would not voluntarily deliver at the terms of trade imposed by the state the quantities desired by the state—i.e., would not voluntarily pay the tax in kind levied by the state—a system of delivery quotas has been necessary to enforce these terms of trade. In addition to meeting the quotas fixed for deliveries at obligatory delivery prices (*tseny obyazatel'nykh postavok*), the collective farms were expected to fulfill “plans” for additional procurements at state purchase prices (*tseny gosudarstvennykh zakupok*). Although the latter were higher than the obligatory delivery prices, they were still below collective farm market prices, and hence sales at state purchase prices were in most cases not voluntary but compulsory [46, pp. 88-91]. In the case of raw material crops, the possibility of collective farm market sales does not exist.

In this light, the turnover tax on agricultural commodities, which accounts for the bulk of the difference between the procurement price paid to collective farms and the retail price charged final consumers, may be thought of as being borne in part by producers in the form of lower procurement prices and in part by consumers in the form of higher resale prices.

The Soviets have long justified procurement prices “below the value” of the commodity on the ground that this is the means by which the state is compensated for expenditures on behalf of the collective farm peasantry for irrigation, conservation, electrification, agricultural research, education and health measures, etc. [48, p. 61] [68, p. 223]. This view in effect interprets that part of the turnover tax borne by the collective peasantry as a charge for specific services rendered to production, together with a contribution to the financing of general welfare expenditures benefiting the peasantry. Another interpretation is that at least part of the turnover tax represents a payment by the collective farms for the use of their land. Although all land in the Soviet Union has been nationalized, it is used by producers without an explicit charge. Soviet writers acknowledge that the state seeks to capture at least part of the differential rent arising from differences in fertility, location, and extent of mechanization through a number of devices. These include regional variations in procurement prices, in obligatory delivery quotas, and (up to 1958) in rates for payments in kind for machine-tractor station (MTS) services, as well as direct taxes on collective farm income [62, p. 573]. The low level of procurement

²⁷ As one Soviet writer puts it: “In other words, purchase prices, besides their direct functional role as an instrument of accounts between the producers of agricultural products and the state, acquire significance as one of the important mechanisms of distribution of the national income between town and country” [65, p. 16].

prices (high rate of turnover taxation borne by the collective farm peasantry) thus represents in part a rent charge by the state as owner of the land and in part a tax imposed by the state to finance its expenditures, both those directly affecting collective farms and those of more general effect.²⁸

The second objective of agricultural procurement prices is, through their general level, to furnish incentives to collective farm peasants to produce agricultural output in general; and through their relative price structure, to furnish incentives to produce certain agricultural products in preference to others. It is evident that this second objective, which would be furthered by higher procurement prices, conflicts with the first one of collecting a tax in kind through low procurement prices. It constitutes an alternative approach to agricultural procurement, stressing price incentives rather than coercive quota demands as the means of securing food and agricultural raw materials from the peasantry.

Allowance for collective farm market sales results in a significant improvement in the peasantry's terms of trade and real income and a marked increase in its incentive to produce, because collective farm market prices have been much higher than state procurement prices [56, pp. 247-48] and because collective farm market sales represent an important share of total marketings, especially for individual peasant households [36, pp. 39, 44]. This is no doubt one of the reasons why the collective farm market has been tolerated by the Soviet state, despite its ideological incongruity. At the same time, it must be assumed that in fixing state agricultural procurement prices some allowance has been made, if only in an approximate and crude way, for the supplementation by collective farm market sales of the low prices paid on deliveries to the state. Cotton growers who could not sell part of their output on the collective farm market had to be compensated fully through state procurement prices, whereas grain and livestock producers were expected to augment their earnings from sales to state procurement agencies by sales, at higher prices, on the collective farm market [41, p. 856].

The interrelationships here are complex, however. While collective farm market prices have no doubt influenced state procurement prices, the converse is also true. The state policy in regard to the prices and quantities of agricultural procurements affects both the supply offered on the collective farm market and the demand on the collective farm market of urban consumers unable to satisfy their requirements at state stores from the state's agricultural procurements. State agricultural procure-

²⁸ It is another matter, however, to attempt to divide actual turnover tax collections among the rent charge and tax components. For a discussion of the problem, see, for example [11, pp. 82-85].

ment prices have been fixed after taking into account the prospects for collective farm market sales and the extent to which *average* realized prices (for food products) would therefore exceed state procurement prices.

2. *Price Policy since 1953.*²⁹ One of the first steps taken by Stalin's successors in 1953 was to embark on a broad program to increase agricultural output, involving changes in planning and administration, delivery requirements, taxes, investment, and prices.³⁰ The changes in agricultural procurement price policy included a large increase in the general level of prices, a revision in the relative price structure in favor of food crops, efforts to calculate costs and to relate prices to costs, and the unification of multiple prices into single procurement prices for each crop.

In 1953, obligatory delivery and above-quota purchase prices were increased sharply for most food products [56, p. 263] [65, p. 24]. In some cases, such as vegetables and potatoes, average realized prices were also raised by reductions in obligatory delivery quotas, which released more of the crop for sale at the higher state purchase and collective farm market prices [53, p. 195].³¹ The 1953 revisions, however, clearly were the result of hasty rule-of-thumb calculations.

The next round of price increases, in 1956, represented the initial response to the cost studies begun in 1955. Most procurement prices were increased again. In some cases the differential between the basic and the higher incentive price for a product was narrowed. For example, sugar beet base prices were raised roughly fourfold while the maximum premium price was reduced from 400 to 150 per cent of base [56, p. 265]. In the case of potatoes, the obligatory delivery price was increased by about 150 per cent and the above-quota purchase price by only 50 per cent [65, p. 17].

The major change in agricultural procurement prices occurred in 1958 in connection with the decision to abolish the MTS's and turn their machinery over to the collective farms. Multiple pricing was eliminated, and a new single state purchase price was fixed for each product. The new prices are supposed to be incentive prices adequate to cover average costs of production, including a reasonable compensation for collective farm labor, and to provide for "accumulation" (i.e., collective farm investment in fixed and working capital).

The general constraint upon the 1958 price increase, as stated by Khrushchev, was that the total bill to the state for procurements from

²⁹ For a discussion of agricultural price policy before 1953, see [46] [56].

³⁰ For a survey of the various measures, see [71].

³¹ Other minor incentive measures involved "return sales" and compensation for expenses of transportation from the farms to procurement points [53, pp. 201-3].

collective farms was not to increase—that is, that the new procurement bill was not to exceed the previous bill for deliveries plus the bill for MTS operations and investment [63, Jan. 25, 1958]. The desired level of turnover tax collections, out of the difference between agricultural procurement prices and state retail prices, also imposes a limit on the general level of agricultural procurement prices. Procurement price increases since 1953, in the face of reductions in retail prices in 1953 and 1954 and general stability in retail prices since then, have required reductions in the turnover tax rates on flour, meat, and sugar, and the elimination of turnover taxes on butter, potatoes, vegetables, and some meat products [68, p. 237]. Moreover, as a result of the 1958 procurement price increases, retail prices on vegetables were raised 10 per cent and on potatoes 8 per cent [65, p. 44]. Further agricultural procurement price increases thus would conflict with the present Soviet policy of maintaining a stable state retail price level.³²

The cost calculations underlying the 1958 prices are of some interest. The cost investigations begun in 1955 faced two kinds of difficulties [56, pp. 256-57] [68, pp. 216-21]. First, basic data were lacking, because the accounts of collective farms and MTS's were not set up to show accurately the expenditures for labor, machine operations, materials, etc., on individual products. There was no accounting category for depreciation. Labor inputs were measured not in money wage payments or even man-days, but in labor-days (*trudodni*), an accounting unit of effort which varied in significance from one product to another, from one farm to another, and from one year to the next. Second, there were conceptual difficulties in valuing machine operations of the MTS's and labor inputs of the collective farmers.

In the case of the former, the collectives made payments in kind for machine operations performed by the MTS's. Before the abolition of the MTS's in 1958, their services for collective farms were valued, in cost calculations for price revisions, either at operating costs (*sebestoimost'*) or in terms of the payments in kind made to the MTS's by the collective farms (variously valued at obligatory delivery prices, state purchase prices, or the farm's own cost of production of them). In comparing collective farm costs following the acquisition of the MTS machinery in 1958 with corresponding costs for earlier years, reported MTS operating costs in those years have been used.

In the case of collective farm labor inputs, payments were made in money and in kind, but the amounts paid in these two forms per labor-

³² " . . . the increase of purchase prices to that level at which it would be impossible to reduce retail prices further or, even more, it would be necessary to raise them, would be, from the point of view of Soviet price policy, inadmissible" [65, p. 18].

day unit earned by a collective farmer varied widely from one farm to another and from year to year on the same farm. Moreover, since payments for a labor-day were greater on the more successful farms, to use actual labor-day payments would have made it appear that the more efficient farms had higher costs! Clearly, for purposes of comparison, some fixed, notional value had to be assigned to labor inputs. The solution adopted was to value labor at state farm wage rates—a procedure which corresponds to the notion that state farms represent a model for collective farms.

The 1958 prices purported to cover average costs³³ of production and to provide for accumulation. A comparison of these prices with average collective farm costs in 1953-56 shows that they substantially exceed production costs of sugar beets, cotton, flax, and wool; slightly exceed production costs of grain, potatoes, and vegetables; and fall notably short of covering production costs of beef, pork, and milk [56, p. 269] [68, pp. 234-35]. The "average costs" considered in fixing these prices are thus not the actual average costs of the immediately preceding years but rather appear to be anticipated feasible costs in the (near?) future in regions from which quota deliveries are required. These are lower than average collective farm costs in the past for two reasons. First, quota deliveries have been eliminated or greatly reduced in exceptionally high-cost areas, and second, cost reductions are expected from the transfer of the MTS machinery to the collective farms.

The prices fixed in 1958 are described as both "stable" and "flexible." They are expected to remain basically unchanged for some time, but annual adjustments up or down will be made for exceptionally bad or good harvests, in order to keep the size of the total procurement bill approximately constant. Thus, a number of prices were reduced for the bountiful 1958 harvest, while potato prices were raised for the 1959 crop.³⁴ Prices will therefore tend to vary from year to year directly with cost, instead of inversely as under the former multiple price system.

The 1958 prices are also supposed to promote a rational pattern of regional specialization in agricultural production. Before 1958, regional differences received only token recognition. Although there was some regional variation in delivery quotas, MTS rates, and prices, the basic principle nevertheless was that every farm, regardless of natural conditions, should deliver some amounts of each of the basic

³³ Some Soviet economists proposed basing prices not on average cost but on cost on marginal land—a suggestion rejected on the ground that it would remove the pressure for cost reductions imposed by average-cost pricing [68, p. 235].

³⁴ For the 1958 crop, the percentage reductions from the "stable" prices were as follows: grain, 13; sunflower seed, 15; sugar beets (unirrigated), 10; and potatoes, 10. The potato price increase in 1959 was 10 per cent [65, p. 25].

food crops—grain, potatoes, vegetables, meat, and milk. Since the prices for these crops failed to cover cost, this principle was in effect a method of requiring all farms to bear part of the burden of the tax in kind. The general principle underlying the regional differentiation of the 1958 prices appears to be that price should be higher in the higher-cost regions, but that the margin of “profit” above cost should be higher in the lower-cost regions. This policy endeavors to secure a continued and perhaps expanded flow of output from the higher-cost regions while providing the greatest incentives (and means) for expansion of output to the lower-cost regions. It is hoped that future growth of output in the latter will eventually make it possible to curtail procurements from high-cost regions and thereby to reduce average costs and hence procurement prices [56, pp. 267-68].³⁵

An appraisal of agricultural procurement price policy since 1953 thus shows clearly a shift to a policy of providing incentives to expand agricultural output. The over-all level of agricultural procurement prices was sharply increased after 1952, while prices of manufactured producer and consumer goods bought by collective farms and individual peasants were reduced, as a result of general reductions in wholesale prices of producer goods in 1955 and in retail prices in 1953 and 1954.³⁶ Although precise calculations of the terms of trade cannot be made from available data, it is clear that they have improved substantially as a result of these price trends.

What is perhaps even more significant is that an effort is now made to set prices on the basis of, or at least with some recognition of, costs.³⁷ However, a comparison of relative prices and relative costs shows that technical crops still enjoy a favored position compared to food crops and that price still fails to cover cost for meat and milk production. The latter reflects the Soviet government’s unwillingness, for internal political reasons, to raise retail prices on these products. The inadequacy of meat and milk prices—together with the still rather low prices for grain, needed for livestock feed—also helps to explain the failure of Soviet agriculture to achieve meat and milk targets during the first few years of the seven-year plan (1959-65) [43, pp. 220-

³⁵ Regional and seasonal price differences are discussed at length in [68, pp. 258-77].

³⁶ Furthermore, since 1958, the collective farms have been permitted to buy at wholesale prices various goods previously sold to them at retail prices, such as motor vehicles, fuel, and hardware [68, p. 239].

³⁷ In addition, price relationships in pre-Revolutionary Russia and price relationships abroad are also reported to be considered in fixing relative prices. “In the process of working out drafts of the new purchase prices, there was submitted to the corresponding government commissions much statistical material about average current procurement-purchase prices for individual products of agriculture relative to each other, and also relative to prices prevailing in 1913 and prevailing in foreign countries at the present time” [65, p. 20].

27]. Thus, although the 1958 prices do represent a significant advance in the use of price incentives, the principle has not been fully applied to livestock producers.

Another objective of the price revisions of 1953-1958 was to reduce the marked inequality in income distribution within the collective farm sector. Due to these revisions, the income of food crop producers improved relative to that of technical crop producers, the disparity in income between the more and the less efficient farms was diminished, and—as a result of these two developments—regional differences in incomes were reduced.

Finally, the increase in collective farm money income has made possible both a large increase in money payments for collective work and a limited shift, on a minority of farms, from residual payments for labor-days to regular monthly wage payments at specified rates. The shift to wages, as part of the program of incentives, will surely tend to increase labor productivity on collective tasks.³⁸ It appears that, with a policy of “stable” agricultural procurement prices, primary reliance will be placed on increases in productivity and reductions in costs from this and other sources (such as the control by the collective farm chairman of the machinery used on the farm) to secure yield increases. Nevertheless, the increased attention of Soviet price-planners to the relationship of prices and costs suggests that further revisions in agricultural procurement prices may be made, subject to constraints imposed by retail price policy, to stimulate the production of lagging crops.

III. Retail Prices

There are two principal types of retail prices at which goods are sold to households in the Soviet Union: state retail prices and collective farm market prices.

State Retail Prices

The state retail price (*gosudarstvennaia roznichnaia tsena*) is charged by state retail stores, consumer cooperative stores, and state and cooperative establishments providing services, such as restaurants, dry-cleaning shops, theaters, etc.³⁹ The consumer cooperatives, which

³⁸ In the opinion of Nimitz [56, p. 275]: “The significance of this trend for labor productivity can hardly be overestimated. Under a wage system using piece rates, the relation between individual effort and reward is direct and certain. When participants share in an uncertain total, the individual incentive to intensify effort is reduced.”

³⁹ Health and education services are, with minor exceptions, provided free of charge. Although a price (rent) is charged in the case of housing, it is recognized not to cover “cost” and which is not intended to demand and clear the market. This explains why housing and utilities (electricity, gas, etc.) constitute only 4-5 per cent of the budgets of

operate primarily in rural areas, are closely supervised by the state, which determines their number, size, location, staff, etc.; allocates goods to them; and establishes sales plans for them. Of total state, cooperative, and urban⁴⁰ collective farm market sales in 1959, the respective percentage shares of the three types were 66.0, 29.3, and 4.7 [67, p. 636].

1. *Objectives.* State retail prices supposedly are fixed with the aim of clearing the market both in aggregate terms and for each commodity. In aggregate terms, the objective is to set the general level of state retail prices so that the total retail sales at that price level will absorb the money income which the population is expected to spend at state retail outlets. For individual goods, the objective is to fix the price of each at a level which equates planned supply and expected demand [48, pp. 159-60].

Soviet planners are reported to fix the general level of state retail prices by comparing two planning "balances," the balance of money incomes and expenditures of the population and the balance of sources and uses of consumer goods and services. The former includes the various sources of money income (wages, pensions, money incomes of collective farmers, etc.) and its disposition (among expenditures on goods and services, direct taxes, bond subscriptions, deposits in savings banks, etc.) The latter compares the several sources of supply of consumer goods (current production, various types of inventories, and imports) and the distribution of this supply (sales to the population, inventories, the armed forces and other state agencies, and exports). From these balances, the planners determine the price level at which planned supplies must be sold to absorb the amounts which households are expected to desire to spend on retail purchases [53, pp. 150-53].

The general level of retail prices depends upon both tax and wage policies. The Soviet government relies primarily on price-increasing taxes—namely, the turnover and profits taxes—to finance investment, defense, and social services. As a result, the general retail price level is higher than it would be if direct taxes were used to a greater extent. Planned increases in private consumption can be distributed among households by reducing retail prices or by increasing money incomes (or by a combination of the two). The first method distributes the increase in consumption among the population as a whole

p. 420]. For a discussion of the multiple state retail price system used in connection with rationing from 1929 to 1936 and during the Second World War, see, respectively, [8, pp. 236-39, 251-52] [72, pp. 72-77].

⁴⁰ Statistics on rural collective farm market sales are not included in published Soviet trade statistics.

(although all consumers may not benefit to the same degree because of differences in the extent to which individual prices are reduced, differences in money incomes, differences in consumption patterns, etc.). The second method, however, is potentially much more selective and discriminatory. With stable retail prices, money wages of different segments of the population can be increased by different degrees (and at different times) to provide selective incentives for increased productivity and for occupational and geographical shifts. Since the Second World War, both methods have been used in turn in the USSR. From 1948 through 1954, retail prices were reduced each spring [18]. Since 1954, the state retail price level has been kept relatively stable, while the money incomes of particular segments of the population have been raised by increases in agricultural procurement prices, pensions, minimum wages, and the wages of selected occupations (e.g., coal miners).

In pricing individual goods so as to clear the market, the planners are reported to consider the cross-elasticities of demand for substitute and complementary goods [53, p. 154]. Under planners' sovereignty in the USSR, the basic mechanism of adjustment to a disequilibrium in the market for a particular good is to adjust demand to supply, in contrast to the adjustment of supply to demand which characterizes the response to consumers' sovereignty. The latter kind of adjustment occurs in the USSR only to a limited extent when, in response to evidence in the form of shortages or surpluses at the prevailing prices, planners modify the composition (types, models, etc.) of the output of the various kinds of consumer goods which can be produced with the resources which they have allocated to those lines of production.

In addition to the fundamental objective of clearing the market, retail prices on individual commodities are also set with other objectives, some of which tend to conflict with the basic objective. One such additional objective, arising from administrative considerations, is to keep prices unchanged (except for authorized seasonal variations) for long periods of time. It is obvious that this goal conflicts with the aim of balancing demand with supply.

Another objective is to make the distribution of real income less unequal than the distribution of money income, by fixing lower prices for mass consumption goods (e.g., basic foodstuffs) which predominate in the budgets of lower-income groups, and higher prices for goods (e.g., consumer durables and luxury foodstuffs) which are relatively more important in the budgets of higher-income groups.⁴¹ In pursuit of this objective, prices of basic food products have deliberately been set and maintained below the equilibrium level, as persistent shortages attest

⁴¹ Thus the turnover taxes responsible for the relatively higher prices of the latter goods are in effect progressive.

[68, pp. 11-12, 66]. Thus, the informal rationing of queues and empty shelves helps to modify the distribution of real income from the initial distribution of money income.

Relative prices are also used to pursue other objectives of social policy. Low prices are set on books, to promote indoctrination and education, and on children's apparel, to aid large families, while high prices are intended to curb the consumption of vodka. In order to discourage home or handicraft production, relatively low prices are set on finished goods, such as baked bread and sewn articles, and relatively high prices on component materials, such as flour and cloth.⁴²

The turnover tax, which provides 40-45 per cent of total budget revenue [67, p. 802], is the principal device used by the planners to secure the desired level and structure of retail prices. The principal components in the state retail price of a commodity are (1) the enterprise wholesale price (or the agricultural procurement price plus the mark-up of the procurement agency), (2) the turnover tax, (3) the wholesale trade margin, and (4) the retail trade margin. In addition, there are transportation charges. The several margins are intended to cover expenses and provide a profit at the respective stages. The shares of enterprise wholesale prices, turnover taxes, and the two trade margins in the total value of state retail sales in recent years may be estimated, respectively, at approximately 50, 40, and 10 per cent [67, pp. 637, 669-75, 799]. Their relative importance in the prices of individual goods differs markedly, however, precisely because of the use of the turnover tax to fix the retail price at the desired level. The sum of the enterprise wholesale price and the trade margins provides a floor below which the retail price should not be set but does not determine what the retail price should be. Instead, given the objective of equating demand with supply (or an alternative objective), the appropriate retail price is obtained by levying a turnover tax of the necessary amount.

The turnover tax serves as a cushion which separates the retail prices paid by households and the wholesale prices received by producing enterprises in industry and agriculture. It permits the planners to alter consumer prices without altering producer prices correspondingly, and vice versa. Thus, retail price reductions need not be accompanied by wholesale price reductions, but may be made at the expense of the turnover tax. The turnover tax separates not only the levels but also the structures of producer and consumer prices, since the different rates of taxation on different goods cause their relative retail prices to differ from their relative wholesale prices.

⁴² For a discussion of problems in fixing the relative prices of specific goods and groups of goods, see [68, pp. 423-53]. For a discussion of regional, seasonal, urban-rural, and other variations in the price of a given good, see [68, pp. 459-86].

2. *Evaluation.* How successfully do state retail prices perform their basic functions of absorbing household money income and of equating demand and supply of individual goods? Certainly, the theoretical principle that these prices should be market-clearing scarcity prices rather than prices based only on cost (as in the case of industrial wholesale prices) is sound. Likewise, the principle that prices should adjust demand to supply, rather than the converse, is consistent with the Soviet concept of planners' sovereignty. Hence the question becomes: How faithfully in practice have Soviet planners implemented these principles? They could not reasonably be expected to achieve equilibrium in the markets for all commodities at every point in time—a feat not attained in free-enterprise economies either. To do this would require almost continuous adjustment of prices, which is not feasible under the highly centralized administration of the Soviet economy. Instead, a more reasonable objective would be to achieve an approximate equilibrium for most goods over a planning period of, say, a year or three or six months. Small disequilibria, between periodic price adjustments, could be met by the depletion or accumulation of inventories (except in the case of services).

However, this is not the approach which Soviet planners have taken. The persistence of shortages (and the unofficial rationing of empty shelves) of many, perhaps most, consumer goods for long periods after the abolition of rationing in 1947⁴³ indicates that the general level of retail prices (i.e., turnover taxation) has been too low relative to the level of wages and other money incomes. The result has been repressed inflation, except to the extent to which the excess purchasing power in the state retail trade sector has found an outlet in the collective farm market. Instead of rationing by a physical allocation system or by the price system, insufficient supplies (at the prevailing prices) have been rationed through such inefficient mechanisms as the queue and influence with shop personnel.

Why has the Soviet government preferred repressed inflation and such rationing mechanisms to an equilibrium price level? One explanation offered by Soviet writers is that shortages stimulate labor productivity because they show that supplies and production are not adequate. This argument is not convincing, however, since high prices would indicate the need for increasing output of consumer goods just as effectively as shop shortages [18, pp. 621-22]. Another reason might be the desire to minimize inventories, which is achieved by low prices which cause shortages to be typical of Soviet retail trade [18, p. 622].

Perhaps the most likely explanation is related to the income distribution objectives discussed above. Just as formal rationing was used in

⁴³ Evidence of widespread and persistent shortages at prevailing prices is provided by the Soviet press. See [18] and almost any issue of the *Current Digest of the Soviet Press*.

the 1930's and 1940's to assure supplies of food, clothing and other basic consumer goods to lower-income groups, so in the 1950's informal rationing devices have been relied upon to enable them to obtain goods which they would be unable to buy at equilibrium prices. Higher-income groups able to pay the higher prices on the collective farm market can thereby avoid the frustration of queues and empty shelves, at least in so far as many food products are concerned. The Soviet leaders evidently prefer this method of rationing, as a means to secure what they regard as a more equitable distribution of scarce goods, to formal rationing, which they apparently consider inappropriate in peacetime, and to a major revision of the distribution of money income, which would have serious implications for incentives. Of course, it could also be argued that shortages were regarded by the Soviet leaders and planners as temporary, and that they expected the supply of goods to "grow up" to the price level in the course of a comparatively few years. It is true that the importance of this informal rationing mechanism has declined since 1954, as supplies of consumer goods have increased, largely as a result of the increase in agricultural production, while the general level of retail prices has remained stable and the wages of lower-income groups have been raised, both in absolute terms and in relation to those of higher-income groups.

The shortages which result from retail prices below the equilibrium level also conceal errors in relative prices which would be evident if the general retail price level were closer to equilibrium. Relative prices become significant only when they correspond to choices which are actually available to consumers. However, when the value of goods offered for sale does approach equality with the intended expenditure of the population, both shortages and surpluses are likely to occur because of errors in relative pricing. The existence of such shortages and surpluses in turn prevents the attainment of general equilibrium, since, under Soviet conditions, prices (or production) are not promptly altered to eliminate disequilibria.

It is not surprising that errors should occur in the fixing of relative prices. One source of error is inaccurate estimates of expected supplies. Supply estimates based on ambitious production targets in agriculture and light industry are likely to prove overly optimistic. In addition, as already noted, the assortment plan for the composition of output is often sacrificed by enterprise managers in order to achieve the gross output and profit targets. This in turn reflects the divorce, by the differentiated turnover tax, of the structure of enterprise wholesale prices from the structure of retail prices: the scarcest goods are not always those which contribute most to the gross value of output or those which are the most profitable to produce.

A second source of error is in the inaccurate estimates of demand.

It is true that for many years information has been collected about family budgets, the structure of retail sales, and price movements on the collective farm market [53, p. 153]. However, demand analysis is as yet a relatively undeveloped branch of Soviet economic science. This reflects the emphasis of Soviet planners on goals other than consumer satisfaction, and the below-equilibrium pricing and widespread shortages of basic consumer goods in the past. Under such conditions, it was not considered important to estimate elasticities of demand with precision.

There have been comparatively few adjustments of relative prices, chiefly involving consumer durables, since 1954, although Soviet writers have criticized the price reductions of 1948-54 as too "automatic" and "mechanical," because they involved uniform percentage reductions for broad categories of goods, without sufficient regard for the relative scarcities of goods or for prices of substitute and complementary goods [48, p. 163] [68, p. 457-59]. It is possible that the limited decentralization in 1957 of the responsibility for setting retail prices may lead to more flexible state retail prices, at least for the goods whose prices are no longer fixed centrally.⁴⁴

However, there are several factors which tend to make many frequent price adjustments unlikely. One is the administrative cost of making such changes under a highly centralized system of economic administration. Another is the impact of retail price changes on the distribution of real income, which the Soviet leaders regard as a political question of primary importance: changes in the prices of bread, meat, and other basic consumer goods are the result of high-level political decisions, not merely of comparisons of expected supply and demand at the technicians' level. Finally, it is through retail prices that the chief source of Soviet budget revenue, the turnover tax, is collected. Changes in retail prices therefore involve fluctuations and uncertainty in tax collections.

Collective-Farm Market Prices

The collective-farm market price (*tsena kolkhosnovo rynka*⁴⁵) of a good is determined by supply and demand in the individual collec-

⁴⁴ Before March 1957, the goods whose prices were fixed by the central authorities in Moscow accounted for more than 90 per cent of total state and cooperative retail trade, while the authorities at the union republic and lower levels fixed the prices on the remainder. In March 1957, the latter were given responsibility for setting prices on a larger list of goods, accounting for about 45 per cent of total sales. However, the central authorities in Moscow retain responsibility for fixing the prices of such important goods as bread, meat, fish, butter, textile cloth, footwear, knit goods, tobacco, vodka, and most durables. The union republic and lower authorities set prices for sausage and confectionery articles, eggs, milk, sewn goods, furniture, toys, and nonalcoholic beverages [68, pp. 475-79].

⁴⁵ Alternatively, *tsena kolkhosnoi bazarnoi i yarmachnoi torgovli* (price of collective farm bazaar and fair trade).

tive-farm markets, varying from market to market and from day to day in the same market. There are about 8,000 collective-farm markets, approximately half of them in towns of various sizes and half in rural areas. The markets occupy designated trading areas and are equipped with a varying number of stalls, benches, tables, storage bins, meat and milk control points, etc. Sellers are charged a small daily fee for the right to offer their wares. Half a million peasants are reported to participate in the markets daily.⁴⁶

Although urban collective-farm market sales were only 4.7 per cent of total state, cooperative, and urban collective-farm market sales in 1959, their importance in Soviet retail trade is greater than this relationship suggests. First, collective-farm market trade consists almost exclusively of food products, while these account for only 45 per cent of state and cooperative trade. Thus, the share of urban collective-farm market trade in total food sales of these ~~three~~ marketing channels was 7.9 per cent in 1959. Second, the collective-farm market deals in a narrower range of food products than state and cooperative outlets. In relation to total trade of the three channels in the same food goods, the collective-farm market share in 1959 was 14.7 per cent. Finally, it would be desirable to compare the urban collective-farm market figure directly with the amount of *urban* state and cooperative trade in the same goods. Data are not available for this comparison for the Soviet Union as a whole. However, a special survey of 25 large cities in 1958 showed that the collective-farm market share in such a comparison was less than 20 per cent in 7 cities, between 20 and 30 per cent in 5, between 30 and 40 per cent in 8, and over 40 per cent in 5 cities. In the last group were the important cities of Odessa, Tbilisi, Rostov-on-Don, Baku, and Tashkent [9].

Although collective-farm market prices are set by supply and demand, both supply and demand are strongly influenced by the state. The demand depends on the extent to which the state retail-trade network is able, with available quantities at the established prices, to satisfy the effective demand of households—i.e., on the excess purchasing power remaining after household expenditures in the state retail trade sector. The supply offered by agricultural producers (collective farms, collective and state farm peasants, and urban workers with garden plots) depends on the size of the deliveries which they are required to make to state procurement agencies and the prices offered by these agencies.

Despite its ideological heterodoxy, the collective-farm market performs several useful functions in the Soviet economic system. On the one hand, it provides an outlet through which some inflationary pres-

⁴⁶ For a discussion of the collective farm market, with particular reference to trends in government policy toward it, see [75].

sure can escape. Although excess demand cannot drive up state retail prices, it can and does raise collective-farm market prices to a market-clearing level. On the other hand, as noted in Section II, the prospect of sales in the collective-farm market at prices above those offered by state agricultural procurement agencies provides an additional and important incentive to agricultural producers to expand output and marketing.

Both of these effects are considered by Soviet planners in fixing the levels and structures of state retail prices and of agricultural procurement prices. The levels of both kinds of prices are lower than they would be in the absence of a collective-farm market to absorb some of the effects of low state retail prices and to offer peasants additional incentives. Likewise, the structure of state retail prices takes into account the availability of certain goods (e.g., raw food products but not clothing) in the collective-farm market, while the structure of agricultural procurement prices takes into account the possibilities for selling certain goods (e.g., meat and vegetables but not cotton) in the collective-farm market. Finally, as a result of the transfer of purchasing power from urban workers to peasants through collective-farm market sales, the structure of demand in the state and cooperative retail trade network is altered, since the goods bought by the two groups differ.

The difference between the collective-farm market price level and the state retail price level has been declining in recent years. A sample for 101 large cities shows that, for major food products sold in the collective-farm market, prices were 31 per cent above the state retail price level in 1959, compared to 45 per cent above in 1956 [66, pp. 773-74] [67, pp. 680-81].⁴⁷ The large difference between the two price levels clearly reflects the substantial extent of below-equilibrium pricing in state retail stores, although in part it also reflects a premium paid for the better quality and freshness of products in the collective-farm market. The decline in the difference between the two price levels over this period appears to be due primarily to the increased availability of goods in state stores and a corresponding easing of demand in the collective-farm market, leading to a smaller quantity of goods being sold at lower prices there [67, p. 709]. Differences between collective-farm market and state retail prices (aside from those due to differences in quality, ease of making purchases, etc.) will disappear only when state retail prices are fixed at equilibrium levels, as a result of increases in state retail prices or in supplies relative to house-

⁴⁷ These relationships do not in themselves provide a reliable indicator of the extent of repressed inflation, however, because they do not take into account the volume of sales in each trade channel and because some of the excess purchasing power of households after state retail purchases is involuntarily saved rather than spent on the collective farm market. On the first point, see [38, p. 170].

hold money incomes. Until then, the collective-farm market may be expected to continue to perform its useful, if ideologically unorthodox, functions.

The state's recognition of this is indicated by its promotion of the commission-trade form of collective-farm market trade. Since 1953, consumer cooperatives have carried on a form of collective-farm market trade in which they act as agents for collective farms and farmers, selling their surpluses for them in the collective farm market for a commission of about 10 per cent [67, p. 708].⁴⁸ In 1959 these commission sales constituted one-fifth of total collective-farm market sales [67, p. 708].

The commission-trade price (*tsena komissionoi torgovli*) of a good is set by the consumer cooperatives on the basis of the prevailing collective-farm market price but always substantially (on the average, 17 per cent) below it. However, commission prices on the average have exceeded the state retail prices for the same goods by about 10 per cent [67, pp. 680-81]. The objectives of the commission trade appear to be to exert pressure on the level of collective-farm market prices and to reduce the amount of time and effort which collective farmers devote to marketing, rather than producing, agricultural output.

IV. Conclusions

What can be concluded from the preceding analysis about the rationality of the Soviet price system? This depends on the concept of "rational prices." At least three concepts can be distinguished:

1. According to Mises, Hayek, and others, rational prices are those determined by consumer sovereignty in a competitive free-enterprise market economy [10, pp. 445-46]. It is clear that by this criterion Soviet prices are not rational.

2. Another concept of rational prices is that they are scarcity prices, i.e., prices which equate supply and demand. Under socialism, such prices could be determined in a decentralized manner by the interplay of the supply and demand of socialist firms and households, or they could be determined in a centralized way by the planners [21, pp. 55-60]. In the latter case, the pertinent demands might correspond to either consumers' or planners' preferences. The planners might strive for *consumer satisfaction*, as distinct from consumer sovereignty, or they might wholly or partly substitute their preferences for those of consumers [10, p. 442] [21, pp. 69-74]. In both cases, equilibrium prices would be relied upon to allocate scarce resources to achieve the ends posited by the ruling preferences. However, while prices can be set to equate supply with demand according to planners' preferences,

⁴⁸ A somewhat similar arrangement existed from November 1946 to August 1949 [68, p. 59].

these preferences cannot themselves be based on an independent calculation of opportunity costs, as reflected in independently determined scarcity prices, since the scarcity prices in use are themselves fixed on the basis of planners' preferences. Instead, the planners' preferences must be formulated on the basis of other economic and political considerations.⁴⁹

By the test of market-clearing prices, Soviet state retail prices are rational at least in principle if not completely in practice, and collective-farm market prices surely are rational. However, agricultural procurement and industrial wholesale prices are not rational, in view of the planners' reliance on delivery quotas in connection with the former and physical allocations in connection with the latter.

3. A third concept of rational prices is that they are prices which perform effectively whatever functions are assigned to them. These functions may include some or all of the following: allocation of resources, provision of incentives, control of enterprise managers, distribution of income, and the implementation of various social policies. For some of these functions, for example control of managerial behavior, rational prices may not need to be scarcity prices. On the other hand, scarcity prices may be used to implement decisions which are not based on scarcity prices, for example, when market-clearing retail prices are used to distribute consumer goods produced as a result of physical planning. Thus, one part of the price system may consist of scarcity prices and another not. Yet both kinds of prices (and the system as a whole) will be rational as long as each set of prices accomplishes whatever the planners desire of it. Ward has called such prices "rational realization prices" [74, p. 140].

How rational are Soviet prices according to this concept, which is essentially that of the Soviet planners themselves? Although industrial wholesale prices are not scarcity prices, they still perform reasonably well their major function of control and evaluation of plan fulfillment. However, because they are not scarcity prices they are not appropriate for even the limited use made of them in resource-allocation decisions by planners and enterprise managers. Hence, according to this concept of rationality, industrial wholesale prices are irrational. Nor can agricultural procurement prices be judged rational by this standard, since they have not evoked the desired supply of agricultural output nor successfully allocated resources among crops within agriculture. Not until 1958 was an effort made to relate agricultural procurement prices to costs, and this relationship is still very imperfect.

⁴⁹ This problem has been identified as the "dilemma" of central planning by Eucken, Montias, and Balassa in their respective studies of the Nazi German [27], Polish [55, pp. 486-87], and Hungarian [6, p. 95] economies.

It is more difficult to assess the rationality of state retail prices. They are in general still (though since 1954 progressively less) below the equilibrium level at which they are supposed to be set. In some cases, for example basic foodstuffs, this appears to be the result of the pursuit of another objective—a deliberate policy of underpricing to affect the distribution of real income. However, a similar justification does not appear to apply in the case of luxury consumer durables, some of which, such as automobiles, are underpriced, while others, such as cameras and watches, are overpriced. Hence, state retail prices cannot be considered completely rational either.

The irrationality of Soviet agricultural procurement prices and state retail prices has been reduced somewhat by price revisions in the past few years. Reform of the price system, especially industrial wholesale prices, has been the subject of intensive discussion among Soviet economists since 1956. The reappraisal of Soviet prices results from the search of the Soviet leaders for ways to increase the efficiency with which available resources are used. The pressure for greater efficiency comes from many sources, including the increasing complexity of choice in a growing and diversifying economy; the higher priority for consumption, formerly the residual sector which absorbed the effects of planning errors; and the effort to devise a sensible pattern of specialization and trade within the Soviet bloc on the basis of comparative costs.

The proposals for reform in industrial wholesale prices range from suggestions for modest changes in the relative prices of selected substitute raw materials to sweeping proposals that the planners use shadow prices which incorporate charges for nonlabor factors and which reflect relative scarcities.⁵⁰ It will therefore be of great interest to see how far the general revision of industrial wholesale prices to be undertaken in 1961-62 goes toward fixing scarcity prices on the basis of which value planning can be assigned a major role in the direction of the Soviet economy.

FORECASTING AND ANALYSIS WITH AN ECONOMETRIC MODEL

By DANIEL B. SUITS*

Although an econometric model is the statistical embodiment of theoretical relationships that are every economist's stock in trade, its discussion has largely been kept on a specialized level and confined to the more mathematical journals. Models are rarely explored from the point of view of their usefulness to the profession at large, yet there is nothing about their nature or their application—aside, again, from a solid grasp of economic theory—that requires anything more than an elementary knowledge of school algebra. The compilation of an econometric model requires a certain degree of technical specialization, but once constructed, any competent economist can apply it to policy analysis and economic forecasting.

The purpose of this article is to present an actual econometric model of the U.S. economy, to demonstrate its use as a forecasting instrument, and to explore its implications for policy analysis. To minimize the technical background required, the presentation is divided into two main parts. Part I deals with the general nature of econometric models, and, using a highly simplified schematic example, illustrates how forecasts are made with a model, how a model can be modified to permit the introduction of additional information and judgment, and how short-run and long-run policy multipliers are derived from the inverse of the model. Part II presents the 32-equation econometric model of the U.S. economy compiled by the Research Seminar in Quantitative Economics. This model is the most recent product of a research project whose initial output was the well-known Klein-Goldberger model [1] [3]. In Part III the outlook for 1962, as calculated and published in November 1961, is studied as an example of an actual forecast; and earlier forecasts of this kind that have been prepared by the Research Seminar annually since 1953 are compared with actual events as a demonstration of the potential of the method.

In Part III the inverse of the model is also presented and its application to policy evaluation is reviewed. Short-run and long-run multipliers are calculated for selected policy variables. Part III also includes

* This is the report of a continuing project of the Research Seminar in Quantitative Economics, sponsored by National Science Foundation grant G-13423. The author is professor of economics at the University of Michigan.

a digression on deficit financing, covering an interesting and important theoretical implication of the model.

I. Econometric Models and Their Applications

The science of economics can be variously defined, but for the present purpose it is useful to think of it as the study of the relationships among a system of observable and essentially measureable variables: prices, costs, outputs, incomes, savings, employment, etc. These relationships derive from the complex behavior and interaction of millions of households, millions of firms, and thousands of governmental units, producing and exchanging millions of products. The relationships can be represented by a system of mathematical equations, but unfortunately a theoretically complete representation (e.g. a Walrasian system) would involve trillions of equations—surely millions for each household and firm. Moreover these equations would be individually as complex as human behavior, and involve the elaborate interaction of numberless variables.

We have neither the time nor the resources to deal with such a vast system of equations; to proceed at all we must simplify and condense. Millions of individual households become a single "household sector," millions of products become a single item of expenditure, e.g., "durable goods." Moreover, complex mathematical relationships among thousands of variables become simple linear approximations involving two or three aggregates. An econometric model of the economy is obtained by confronting these highly simplified equations with data arising from the historical operation of the economic system and, by appropriate statistical techniques, obtaining numerical estimates for their parameters.

The minimum number of equations necessary for an adequate representation of the economic system depends on a number of considerations, but clearly the fewer the equations the greater must be the level of aggregation and the less accurate and useful the result. On the other hand, the larger the number of equations and the greater the detail shown in the variables, the more complicated it is to derive the individual equations, to manipulate the resulting system, and to see the implications of the model. Where modern computing facilities can be used the mere size of the model is no longer a serious barrier to its effective application, but for purposes of exposition the smaller and simpler the model the better.

A. A Simple Illustrative Example

To illustrate the principles of application, let us suppose that the statistical procedure gave rise to the following, purely schematic, model of four equations.

$$(1) \quad C = 20 + .7(Y - T)$$

$$(2) \quad I = 2 + .1Y_{-1}$$

$$(3) \quad T = .2Y$$

$$(4) \quad Y = C + I + G$$

According to equation (1), consumption (C) depends on current disposable income ($Y - T$). In equation (2), investment (I) depends on income lagged one period. The third equation relates taxes (T) to income, while the last defines income as the sum of consumption, investment and government expenditure G .

While this model is small, it illustrates most of the properties of the larger model. The single consumption function in equation (1) corresponds to the set of four equations (01), (02), (03), and (04) that describe the behavior of the consumer sector in Part II. The investment behavior represented in (2) corresponds to equations (05), through (10). The single tax equation (3) corresponds to a combination of the eleven tax and transfer equations, while the relationship of production to income embodied in equation (4) is indicated in much greater detail by equations (11) through (20).

This econometric model approximates the economy by a system of equations in which the unknowns are those variables—income, consumption, investment, and tax yield—whose behavior is to be analyzed. The “knowns” are government expenditure and lagged income. When projected values for the “knowns” are inserted in the equations, the system can be solved to forecast the values of the unknowns.

Quotation marks are used advisedly on the word “knowns.” For, while some economic variables move so slowly along secular trends that their future values can be projected with considerable accuracy, others—for example new government expenditures—are unknown in advance of their occurrence, even in principle. Moreover, even the values of lagged variables are unknown at the time of the forecast, since a useful forecast must be made some months before the end of the preceding year. For example, each of the forecasts shown in Table 3 (p. 123) was made during the first week of November of the preceding year. To make such forecasts, lagged variables are estimated from data for the first three quarters of the year, with the third quarter given double weight.

At any rate, suppose we expect next year's government expenditure to be 20, and the preliminary estimate of this year's income is, say, 100. Substituting $G=20$ and $Y_{-1}=100$ into the equations above and solving gives $C=86.2$, $I=12$, $T=23.7$, $Y=118.2$.

B. *Introducing Outside Information*

It may appear from the foregoing that this kind of forecasting is a blind, automatic procedure; but while an econometric model looks like

a rigid analytical tool, it is actually a highly flexible device, readily modifiable to bring to bear additional information and judgment. For example, the investment equation in our little model is surely an unreliable predictor of capital formation. If no other information were available the equation would have to serve the purpose. But suppose we have available a survey of investment intentions reported by business. An estimate derived from such a survey is clearly superior to any that equation (2) could produce. To introduce the information into the forecast we simply remove equation (2) from the model and, in the remaining equations, set I equal to the survey value. Forecasts made from the Research Seminar model have frequently involved use of a figure for gross investment in plant and equipment derived from the McGraw-Hill Survey of Investment Intentions rather than from equation (05) of the model.¹

Information can also be used to modify individual relationships short of replacing them entirely. For example a prospective improvement in consumer credit terms—a variable that does not appear in our schematic model—would be expected to stimulate consumption expenditure. It is often possible to set an upper limit to this stimulating effect, and by increasing the constant term in the consumption function by this amount, to set an upper limit to the forecast economic outlook. An adjustment of this kind was applied to equation (01) to allow for the probable influence of the compact car on the outlook for automobile sales during 1960. For the same forecast, a similar modification of the housing starts equation (06) was made in anticipation of activity of the Federal National Mortgage Association.

Using the flexibility to full advantage permits the forecaster to explore any desired number of alternative sets of projections and modifications, and to bring to bear all information and judgment he possesses. The econometric model is not, therefore, a substitute for judgment, but rather serves to focus attention on the factors about which judgment must be exercised, and to impose an objective discipline whereby judgment about these factors is translated into an economic outlook that is consistent both internally, and with the past observed behavior of the economic system.

C. *The Inverse Matrix*

In principle, the exploration of a range of alternative projections and other modifications of the model consists of inserting each set of alternatives in turn as “knowns” in the equations and solving for the resulting

¹ The McGraw-Hill Survey of Investment Intentions is conducted annually in the fall. It becomes available just in time to be incorporated in the forecast presented before the Conference on the Economic Outlook, held annually during the first week of November at the University of Michigan. For several years the Conference has been the occasion for the release of the data by *Business Week*.

forecast. The process is greatly expedited by further simplifying the model and by the use of the inverse matrix. Simplification of the model is made possible by the fact that one of the unknowns, I , depends only on knowns. I helps to determine the current values of C , T , and Y , but the latter do not, in turn, feed back into the determination of the current value of I . As a result, once the knowns are given, I can be directly calculated from (2) without reference to any other part of the model, and hence, as far as the remaining equations are concerned, I can be treated as a known in the sense used above. (Indeed it is this fact that enables us to replace equation (2) with survey values for I .)

The process of solving the system of equations can then be divided into two parts. First: using the values of the knowns, calculate the value of I . Second: substitute the knowns (now including I) into the remaining equations, and solve for the other unknowns.

The inverse matrix facilitates the second step. For those unfamiliar with matrix manipulations the following will help clarify the nature and use of this table. Since I is now considered as known, the model is reduced to the system of three equations (1), (3) and (4) above. By transferring all unknowns to the left side, and representing the right sides by P_1 , P_3 , and P_4 , these equations can be expressed as:

$$(1) \quad C - 0.7Y + 0.7T = 20 = P_1$$

$$(3) \quad -.2Y + 1.0T = 0 = P_3$$

$$(4) \quad -C + Y = I + G = P_4$$

Now using any convenient method to solve this system for C , Y , and T in terms of P_1 , P_3 , and P_4 will yield:

$$C = 2.273P_1 - 1.591P_3 + 1.273P_4$$

$$T = .445P_1 + .682P_3 + .455P_4$$

$$Y = 2.273P_1 - 1.591P_3 + 2.273P_4$$

That is, the value of each unknown is obtained as a specified weighted total of P_1 , P_3 , and P_4 . Where a large number of equations is used, and a lot of calculating is to be done, it is convenient to display the weights used for each unknown as a column of numbers in a table, with the detail of the P 's shown in a separate column at the right:

Equation No.	C	T	Y	P
(1)	2.273	.455	2.273	20
(3)	-1.591	.682	-1.591	0
(4)	1.273	.455	2.273	$I + G$

To make a forecast we first substitute Y_{-1} into equation (2) and solve for I . Then I and G are substituted in the P column of the table and the

values of P_1 , P_3 and P_4 calculated. These values, weighted by the numbers shown in the C column of the inverse and summed, give the forecast value of consumption; use of the weights in column Y gives the forecast for income, etc.² For example if we set $Y_{-1}=100$ and $G=20$, we first find from (2) $I=12$. Substituting these values in column P of the table gives the forecast values: $C=86.2$, $T=23.7$, $Y=118.2$.

D. *Short-Run Policy Multipliers*

It is an obvious step from economic forecasting to short-run policy analysis. To investigate any specified set of prospective government actions, we insert them in the proper place in column P and solve for the forecast implied by these assumptions. The analysis is expedited if we first calculate short-run multipliers for the individual components of government action. These can then be applied in any desired policy mixture.

Short-run multipliers for any policy variable are readily calculated by inserting $+1$ for the variable everywhere it appears in column P , and then (ignoring all terms that do not contain the variable in question) extending a forecast using the columns of the inverse. For example, to calculate the government expenditure multiplier, set $G=1$ in row (4) of column P . This makes $P_4=1$. To find the effect of this value of G on, say, income, multiply this value of P_4 by the weight in row (4) of the Y column to get $Y=1 \times 2.273=2.273$. That is, the income multiplier on government expenditure is 2.273. Likewise, $T=1 \times .455=.455$. That is, the tax-yield multiplier on government expenditure is .455. In other words, for every dollar of additional government expenditure, tax receipts rise by nearly 46 cents. A corollary is that—according to our schematic model—an increase in government expenditure of 1 with no change in tax legislation will generate an increase in deficit of only:

$$G - T = 1 - .46 = .54$$

In addition to changing the value of exogenous variables like government expenditure, government policy can produce changes in the equations themselves. An extensive change—e.g. a substantial alteration in tax rates—can only be studied by replacing the old tax equation by a new one, but less extensive changes can be studied as shifts in the levels of existing equations, the coefficients being unaltered.

Multipliers for such shifts are easily determined by placing $+1$ in the row of column P that corresponds to the equation being shifted. The extensions are then made as before. For example, to calculate the multipliers on a $+1$ shift in the level of the tax equation, we put $+1$ in the row marked (3) of column P , since the tax equation is (3). The multi-

² As those familiar with matrix algebra will recognize, the inverse matrix is tabulated here in its transposed form, and goes into the P vector at the right column by column.

plier effect of this shift is then calculated by multiplying this 1 by the weight in the corresponding row of the appropriate column, as shown above. For example for income:

$$Y = 1 \times (-1.591) = -1.591$$

For consumption:

$$C = 1 \times (-1.591) = -1.591$$

In other words, the multipliers associated with the shift of any equation are merely the weights in the row of the inverse corresponding to that equation.

Note that according to our simplified model, the tax-yield multiplier is .682. That is, an upward shift of \$1 billion in the tax *schedule* actually increases *yield* by only \$682 million. The difference is due to the decline in income arising from the shift in the tax schedule.

The small size of our illustrative model limits the policy variables to government expenditure and the level of taxes. In the more extensive model below, policy is given considerably more scope; a number of individual tax and transfer equations can be shifted, and a number of different kinds of expenditure altered. The number of possible combinations of action is correspondingly very large; but one important advantage to a linear system lies in the fact that once multipliers for the individual components have been calculated, the economic implications of a complete policy "package" can be estimated by summing the effects of the individual components.

For example, an increase of \$1 in government expenditure coupled with an upward shift of \$1 in the tax schedule would generate a change in income given by the sum of the two individual multipliers:

$$Y = 2.273 - 1.591 = .682$$

This is what might be called an "*ex-ante*-balanced" government expenditure multiplier. That is, the change in the law is such as to increase tax yield at the *existing* level of income by enough to balance the planned expenditure, but the budget will not necessarily be balanced *ex post*. The tax and expenditure program will alter income, and hence will change tax yields. Analysis of the complete fiscal impact of the operation requires the examination of all revenue and outlay items combined. Adding together the two tax-yield multipliers we find that the additional expenditure of \$1 is offset by a tax yield of:

$$.682 + .455 = 1.137$$

That is, the *ex-ante*-balanced expenditure of \$1 billion would, in our example, be accompanied by an increase of \$1.137 billion in tax yield and give rise to an *ex-post* surplus of \$137 million.

E. Dynamics and Long-Run Multipliers

An increase in government expenditure of 1.0 will increase income by 2.273 the same year. But the long-run effect of expenditure sustained at this level will differ from this. According to equation (2), an increase in income this year will generate an increase in investment next year. This will again raise income and add further stimulus the following year, etc. Once the inverse has been tabulated, however, the sequence can easily be calculated by inserting the forecast values of one year as the "knowns" of the next. Thus an initial increase in G of 1 will raise Y by 2.273. This will raise I by $.2 \times 2.773 = .455$ the following year. The value of P_4 is then $G + I = 1.455$ and the second year income rises to 3.307 above its initial value, etc. The five-year sequence of values would be:

Year	1	2	3	4	5
Income	2.273	3.307	3.775	3.989	4.087

This means, for example, that if government expenditure is increased by 1 in 1961, and sustained at that new level, the level of income in 1965 will—other things equal—be 4.087 higher than it was in 1960.

Similar sequences can be worked out for other policy variables. For example a shift of 1 in the tax schedule in year 1 would imply the following sequence of annual income values:

Year	1	2	3	4	5
Income	-1.591	-2.314	-2.643	-2.793	-2.862

Like short-run multipliers, these long-run multipliers can be combined by simple addition. For example, a permanent rise of 1 in government expenditure coupled with an *ex-ante* shift of 1 in the tax schedule would raise income by $2.273 - 1.591 = .682$ the first year. After 5 years, however, income would be $4.087 - 2.862 = 1.225$ higher than its initial level.

Although the discussion has been focused on a highly simplified example, the principles developed apply equally to any linear econometric model. The presentation of the actual Research Seminar model in Part II will follow the same pattern as the illustration of Part I.

II. The Model of the U.S. Economy

The model developed by the Research Seminar in Quantitative Economics consists of 32 equations, most of them least-squares linear regressions fitted to annual first differences in the variables.³

³ The exceptions are definitional equations, and those approximating tax laws. Use of least squares is unnecessary for the former, and inappropriate to the latter. The frequency of change in tax laws makes past data irrelevant to their current analysis. Tax equations were fitted by eye through a few relevant points.

Five advantages are gained by the use of first differences. In the first place, the autocorrelation of residuals from time series regressions causes a downward bias in calculated standard errors, giving an exaggerated appearance of precision to the result. The use of first differences serves to reduce this bias. Secondly, many of the equations—e.g. the demand for consumer durables—involve stocks for which data are not currently available. The increase in a stock is composed of current acquisitions less retirements. Since the latter tends to be a smooth series, exhibiting little year-to-year variation, the first difference in stock is well represented by acquisitions, a figure readily available on a current basis. Thirdly, in short-run analysis and forecasting, the present position is known, and *ceteris paribus* will continue. The important question is what change from that position will result from projected changes in other factors. The use of first differences serves to focus the power of the analysis on these changes. Fourthly, the use of first differences minimizes the effect of slowly moving variables such as population, tastes, technical change, etc., without explicitly introducing them into the analysis. The net effect of changes in these factors is represented in the constant term of the equation. Finally, use of first differences minimizes the complications produced by data revision when the model is applied. Revisions usually alter the level at which variables are measured, rather than their year-to-year variation.

In calculating the equations, the prewar and postwar periods were explored separately to determine whether there was any indication of a change in the coefficients. Except for institutional relationships—tax laws, transfers, etc.—no important shifts were discovered. Nevertheless the final equations are fitted only to data drawn from the period 1947–1960 to maximize their applicability to current problems.

The equations of the model are presented and discussed below by sectors, and the symbol for each variable is explained the first time it appears. In general the variables correspond to the magnitudes as given in the national accounts, measured in billions of 1954 dollars. In calculating the equations, however, all imputations were removed from the Department of Commerce figures for consumer expenditure and disposable income. These imputations, mainly associated with services rendered by financial institutions and by owner-occupied dwellings, are added back in after a forecast is made to maintain comparability with the national accounts. First differences are indicated throughout by prefixing Δ to the symbol of the variable. Note, however, that lagged undifferenced values of certain variables appear at some points (e.g. in the automobile demand equation (01) below). These undifferenced values serve as proxy variables for first differences in stocks as explained above. Figures in parentheses are the standard errors of the regression coefficients.

A. *Aggregate Demand*

1. Consumption

(01) Automobiles and Parts:

$$\begin{aligned}\Delta A = & .177 \Delta(Y - X_u - X_f - X_s) - .495 A_{-1} \\ & (.086) \qquad \qquad (.168) \\ & + .260 \Delta L_{-1} + 4.710 \\ & (.082)\end{aligned}$$

Consumer expenditure for new and net used automobiles and parts (ΔA) depends on disposable income (Y), net of transfers for unemployment compensation (X_u), and other federal (X_f) and state (X_s) transfers. These transfers are deducted on the ground that they are unlikely to find their way into the automobile market. Servicemen's insurance dividends (X_{si}) are not deducted from disposable income. In addition, automobile demand depends on the stock of cars on the road (A_{-1}) and on the real value of consumer liquid assets at the end of the preceding year (ΔL_{-1}). For this purpose liquid assets are defined as household holdings of currency and demand deposits plus fixed-value redeemable claims as estimated by the Federal Reserve Board. The sizeable constant term in the equation probably reflects replacement demand.⁴

(02) Demand for Other Durables:

$$\begin{aligned}\Delta D = & .176 \Delta Y - .0694 D_{-1} + .0784 \Delta L_{-1} + .262 \\ & (.015) \qquad (.029) \qquad (.016)\end{aligned}$$

This equation relates ΔD , consumer expenditure for durables (other than automobiles and parts) to disposable income (ΔY), the accumulating stock of durables (D_{-1}) and liquid assets.

(03) Demand for Nondurable Goods:

$$\begin{aligned}\Delta ND = & .224 \Delta Y + .205 \Delta ND_{-1} + .143 \Delta L_{-1} - .149 \\ & (.060) \qquad (.135) \qquad (.059)\end{aligned}$$

Nondurable expenditure depends on disposable income, liquid assets, and last year's nondurable expenditure (ΔND_{-1}). Notice the difference between this and the foregoing equations. In (01) and (02) the lagged values were undifferenced representing accumulation of stock. In this equation the difference itself is lagged, representing a dynamic adjustment in nondurable expenditure: an initial rise in level is followed by a subsequent secondary rise.

(04) Demand for Services:

$$\begin{aligned}\Delta S = & .0906 \Delta Y + .530 \Delta S_{-1} + .0381 \Delta L_{-1} + .363 \\ & (.029) \qquad (.170) \qquad (.029)\end{aligned}$$

This equation is similar to (03) and relates expenditure for services

⁴ This equation is a simplified version of that given in [5].

may lose its role in the model.⁶ The term HS_{-1} , the lagged undifferenced value of housing starts, only partially represents the effect of this accumulation, and equation (06) is probably due for revision.

(07) Housing Expenditure:

$$\Delta H = .125 \Delta HS + .024 \Delta HS_{-1} + 6.580 \Delta C + .083$$

(.013) (.012) (5.42)

Expenditure on housing, (ΔH), depends on the rate at which residential construction is carried forward, and thus on current and lagged starts. In addition it depends on construction costs. The term ΔC is the ratio of the index of construction costs to the *GNP* deflator.

(08) Durable Goods Inventory:

$$\Delta ID = .291 \Delta(A + D) + .591 \Delta PD + .305 \Delta M_{+1} - .669 ID_{-1}$$

(.100) (.157) (.085) (.109)

Accumulation of durable inventories, ΔID , depends on sales of consumer durables, producers durables ΔPD , and the stock of inventory already accumulated ID_{-1} . In addition an important component of inventory is associated with government military orders. Production on such orders appears in the national accounts as goods in process, and exerts a strong impact on the economy long before delivery of the finished product materializes as government expenditure. A wide variety of arrangements and lead times are involved in this process.⁷ As a proxy for such orders in any given year, we use ΔM_{+1} , federal military purchases from private industry the following year.

The equilibrium sales-inventory ratio implied by this equation compares favorably with that observed from other data.

(09) Nondurable Goods Inventory:

$$\Delta IND = .427 \Delta ND - 1.121 IND_{-1}$$

(.111) (.248)

Accumulation of nondurable inventory, ΔIND , depends on consumer sales of nondurables and the stock already on hand, IND_{-1} .

(10) Imports:

$$\Delta R = .0602 \Delta G^* + .369$$

(.03)

This relates the aggregate level of imports to the private GNP (G^*).

3. Private Gross National Product

$$(11) \Delta G^* = \Delta(A + D + ND + S) + (\Delta F - \Delta R) + \Delta ID + \Delta IND$$

$$+ \Delta PE + \Delta H + \Delta g$$

⁶ Guttentag argues that this is not necessarily the case [2, p. 297].

⁷ For an excellent study of these see [6].

Private GNP is defined as the sum of its parts including net exports ($\Delta F - \Delta R$) and government purchases from private firms (Δg).

B. *Income and Employment*

(12) Wage and Salary Workers, Private Sector:

$$\Delta E = .068 \Delta G^*$$

This production function, relating ΔE , the number of full-time equivalent employees in the private sector (measured in millions of persons) to the private GNP, applies specifically to the forecast of 1962 and is based on the first three quarters recovery experience during 1961.

(13) Unemployment:

$$\Delta U = \Delta LF - \Delta E_0 - \Delta E_G - \Delta E$$

Unemployment is the difference between labor force (ΔLF) on the one hand, and the number of self-employed and unpaid family workers, (ΔE_0), government workers, including armed services (ΔE_G) and employees of private industry (ΔE).

(14) Average Annual Earnings:

$$\Delta w = - .0216 \Delta U + .00436 P^*_{-1} - .0743$$

(.0076) (.0025)

Δw , average annual earnings (including wages and salaries plus "other labor income," and measured in thousands of dollars) is related to unemployment and last year's profits. This relationship reflects two facts. First and probably more important, annual earnings are heavily influenced by overtime pay which varies inversely with the level of unemployment. Secondly, pressure of union demands varies directly with profits and inversely with the level of unemployment. The undifferenced level of profits is used since the *existence* of profits acts as a target for wage demands.

(15) Private Wage Bill:

$$\Delta W = \Delta(wE) = w_{-1} \Delta E + E_{-1} \Delta w$$

By definition the wage bill is the product of average earnings and employment. To keep the model linear, this nonlinear relationship is replaced by the linear approximation shown.

(16) Depreciation:

$$\Delta Dep = .0456 \Delta G^* + .763$$

(17) Property Income:

$$\Delta P = \Delta G^* - \Delta W - \Delta Dep - \Delta T_{fc} - \Delta T_{cd} - \Delta T_{bp} \\ - \Delta T_{ss} - \Delta T_{os} - \Delta SI_r$$

Property income (ΔP) is a residual from the GNP after deducting wage costs, depreciation (ΔDep), employer contributions for social insurance (ΔSI_r), and indirect business taxes: federal excises (ΔT_{fe}), customs duties (ΔT_{ca}), business property (ΔT_{bp}), state sales (ΔT_{ss}), and other state taxes on business (ΔT_{os}).

(18) Corporate Profits:

$$\Delta P^* = .902 (\Delta P - \Delta P_f) - 1.027$$

This relates profits (ΔP^*) to total property income net of farm income (ΔP_f). There is, of course, no strong theoretical basis for the particular distribution of corporate business found in the U.S. economy. This equation is an empirical representation of the distribution of property income under existing institutional arrangements.

(19) Dividends:

$$\begin{aligned} \Delta Div = & \frac{.229}{(.064)} (P^* - T_{fe} - T_{sc}) \\ & + \frac{.0198}{(.052)} (P^* - T_{fe} - T_{sc} - Div)_{-1} - .0191 \end{aligned}$$

Current dividends (ΔDiv) depend on current profits after federal (T_{fe}) and state (T_{sc}) corporate profits taxes, and on last year's level of undistributed profits.

(20) Disposable Income:

$$\begin{aligned} \Delta Y = & \Delta W + \Delta W_g + (\Delta P - \Delta P^*) + \Delta Div + \Delta i_g + \Delta X_u + \Delta X_f + \Delta X_s \\ & + \Delta X_{gt} - \Delta T_{fy} - \Delta T_{sy} - \Delta T_{eg} - \Delta T_{op} - \Delta SI_e + \Delta T_{ref} \end{aligned}$$

Disposable income is the sum of wages, including government wages (W_g), noncorporate property income ($\Delta P - \Delta P^*$), dividends, government interest payments (i_g), plus transfers, less personal taxes: federal (ΔT_{fy}), and state (ΔT_{sy}) income, estate and gift (ΔT_{eg}), other personal taxes (ΔT_{op}) and personal contributions for social insurance ΔSI_e , all net of tax refunds ΔT_{ref} .

C. Taxes and Government Transfers

1. Federal Taxes

(21) Federal Corporate Profits Tax:

$$\Delta T_{fe} = .500 \Delta P^*$$

(22) Federal Personal Income Tax Receipts:

$$\Delta T_{fy} = .111(\Delta W + \Delta W_g) + .150(\Delta P - \Delta P^* + \Delta i_g) + .195 \Delta Div$$

This equation relates income tax receipts in the form of withholding, quarterly payments on estimated tax, and final tax payment to the sev-

eral income components. The coefficients reflect both variation in income shares by tax bracket and the effect of the dividend tax credit.

(23) Federal Personal Income Tax Liability:

$$\Delta T_{fu} = .100(\Delta W + \Delta W_G) + .114(\Delta P - \Delta P^* + \Delta i_G) + .154\Delta Div$$

Tax receipts commonly exceed liability. The difference (ΔT_{ref}) appears as a tax refund the following year.

(24) Federal Excise Taxes:

$$\Delta T_{fe} = .099\Delta A + .011\Delta D + .003\Delta ND + .010\Delta G^* + .015\Delta Y$$

(25) Customs Duties:

$$\Delta T_{cd} = .083\Delta R + .012$$

2. State and Local Taxes

(26) State Corporate Income Taxes:

$$\Delta T_{sc} = .019\Delta P^*$$

(27) State and Local Sales Taxes:

$$\Delta T_{ss} = .033(\Delta A + \Delta D + \Delta ND + \Delta S)$$

(28) State and Local Personal Income Taxes:

$$\Delta T_{sy} = .010(\Delta W + \Delta W_G + \Delta P - \Delta P^* + \Delta Div + \Delta i_G)$$

3. Social Insurance Programs

(29) Private Employer Contributions for Social Insurance:

$$\Delta SI_r = .149\Delta E$$

(30) Personal Contributions for Social Insurance:

$$\Delta SI_e = .129(\Delta E + \Delta E_G) + .050(\Delta P - \Delta P^*)$$

(31) Covered Unemployment:

$$\Delta U_c = .675\Delta U - .140(\Delta LF - \Delta LF_{-1})$$

The relationship of unemployment covered by compensation programs (ΔU_c) to total unemployment varies with the rate of increase in the labor force. When the labor force is growing rapidly, new entrants, not yet covered, make up a larger proportion of total unemployment.

(32) Unemployment Compensation:

$$\Delta X_u = 1.77 \Delta U_c + .101$$

III. *The Model as a Forecasting Instrument*

A. *The Forecast of 1962*

The unknowns of the model are the 32 variables like automobile demand, disposable income, private GNP, etc. that stand on the left side of the equations. The knowns are variables like government pur-

^a Based on McGraw-Hill survey showing 4 per cent increase in plant and equipment expenditure.

^b FHA ceiling rates are projected at their present level throughout 1962. The projected decline reflects the fact that they were above this level in early 1961.

chases from private firms, labor force, household liquid assets, etc. that appear only on the right side of the equations, and whose values must be projected or assigned before the unknowns can be forecast.

The forecast of 1962, calculated and presented in November 1961, employed the projected values shown in Table 1. The most important single item was the \$16.9 billion increase in consumer holdings of liquid assets. A few of the other key items were: a \$6.9 billion projected increase in government purchases from private firms; an increase of .6 million in government employment; increase in government wage pay-

ments of \$1.5 billion; and a \$1 billion rise in military orders. Note that investment in plant and equipment is projected directly on the basis of the McGraw-Hill survey rather than from equation (05). All monetary values are in 1954 dollars.

When the projections of Table 1 were inserted in the equations, the solution gave the outlook for 1962 shown in Table 2. The first two columns contain a detailed comparison of the forecast of 1961 with the preliminary actual values. The middle column contains the solutions obtained from the equations. These are in first differences and are expressed as increases over 1961. When the forecast increase is added to the preliminary actual level for 1961 the result is the forecast level of 1962 shown in the fourth column. In the last column this forecast has been translated into approximate 1962 prices.⁸

The forecast entails substantial increases in consumption expenditure, especially for automobiles. The forecast level of \$18.8 billion for this sector constitutes a record level of automobile sales, exceeding the \$17.9 billion reached in 1955. This large increase derives primarily from the high level of consumer liquidity and the small addition to stocks of cars during 1961.

Aside from the consumer sector the main stimulus to the economy derives from projected increases in government outlays, associated with the trend of state and local expenditures and federal defense expenditure. In preparing the forecast no allowance was made for the possible effect of a steel strike during 1962. Inventory accumulation in anticipation of interruption of steel supplies will probably accelerate inventory accumulation in the first half of the year and depress it in the second half. There is no indication that this will alter the over-all level for the year.

The forecast increase in production is adequate to absorb more than the growth of the labor force, and the outlook concludes by showing a reduction of 1.3 million in unemployment, reducing the average for the year to 3.6 million or 5 per cent of the civilian labor force.

B. Review of Past Forecasts

The Research Seminar in Quantitative Economics has been making annual forecasts since 1953, each a matter of record published in advance of the year forecast. The econometric model has been revised and improved several times over this period (the version presented here was first used for the 1962 forecast), but the review of past forecasting performance in Table 3 will illustrate the general reliability of the method.⁹

⁸ To convert the values from 1954 to 1962 prices they were multiplied by deflators obtained by raising 1961 deflators $1\frac{1}{2}$ per cent across the board. The result serves to put the forecast in proper perspective, but should not be thought of as part of the forecast itself.

⁹ The review of the 1961 forecast, compared with the actual outcome, is provided in Table 2.

TABLE 2—REVIEW OF 1961 AND OUTLOOK FOR 1962
(Monetary figures, except column 5, are billions of 1954 dollars)

	1961		Forecast Increase	Forecast 1962	
	Forecast	Actual ^a		(1954 prices)	(1962 prices)

^a Preliminary.

^a Includes imputed services.

^b Annual average.

Each forecast is shown as it was presented, and compared with the actual outcome.¹⁰ Note that from 1953 to 1956 the figures are given in 1939 dollars; thereafter the price level employed was changed almost every year. The increasing elaboration of the model is evident in the table.

As plotted in Figure 1, the general accuracy of these forecasts speaks for itself. The direction of movement was correctly forecast each year,

¹⁰ Since data revisions occur frequently, there is some question as to what figures should be taken as "actual." Since we want the "actual" figures as close as possible in definition and economic context to the data on which the forecast was based, they are taken from the issue of the *Survey of Current Business* appearing in the February following the forecast year. E.G. the "actual" GNP for 1954 is the value for 1954 published February 1955.

and the levels were generally well predicted. The recession of 1954 was forecast with considerable precision. The recovery of 1955 was likewise forecast, but the magnitude of the boom that developed was grossly underestimated. The fact that the error of the 1955 forecast is concentrated in the consumer sector lends support to the idea that this was a consumer-generated movement. The recession of 1958 was well predicted. The recovery of 1959 was somewhat underestimated.

In many respects the forecast of 1960 was the most interesting of all. Made in November 1959 at the height of business optimism, and amidst

FIGURE 1. COMPARISON OF FORECAST WITH ACTUAL CHANGES IN GNP (1953-61)
(billions of 1954 dollars)

general anticipation of the "soaring 'sixties," its pessimistic outlook for 1960 was greeted with almost complete skepticism, but it proved to be more exact than any other forecast placed on record in advance.

C. Short-Run Policy Multipliers

Simplification of the model is carried out as illustrated in Part I. Inspection shows that in equation (05), plant and equipment expenditure (ΔPE) depends only on "known" values: last year's profits after taxes, and the stock of plant and equipment available at the beginning of the year. Similarly in equations (06) and (07), housing starts (ΔHS) and expenditure for nonfarm residential construction (ΔH) depend only on credit availability, construction costs, last year's starts, and the stock of houses at the beginning of the year. To make a forecast, therefore, we

use the knowns to estimate ΔPE , ΔHS , and ΔH via equations (05), (06), and (07), and then use these values, together with the other knowns, to solve the remaining equations. The inverse of the model is shown in Table 4. This is merely an enlarged version of the little table shown earlier for the illustrative model of Part I, and is used in the same way. For example, if the projected values of Table 1 are inserted in column P of Table 4, multiplied by the weights in the Automobile column and summed, the result is 4.5, the forecast increase in automobile demand shown in Table 2.¹¹ Short-run multipliers for any policy variable are readily calculated as before by inserting 1 for the variable everywhere it appears in column P and then (ignoring all terms that do not contain the variable in question) extending a forecast using the columns of Table 4.

For example, to find the multiplier on government purchases from private firms, set $\Delta g = +1$ everywhere it appears in column P. The term Δg is found in only one place: in row (11) it is multiplied by 1. To find the effect of $\Delta g = \$1$ on, say, private GNP, we multiply the weight in row (11) of the GNP column by 1:

$$\Delta G^* = 1 \times 1.304 = 1.304$$

That is to say, the short-run multiplier on government purchases is about 1.3. Similarly, the effect on, say, automobile demand is given by

$$\Delta A = 1 \times .092 = .092$$

i.e. the short-run "automobile demand multiplier" on government purchases from the private sector is .092.

In working out a policy multiplier, care must be taken to include changes in *all* exogenous variables affected by the policy action. For example, an increase in government employment involves hiring additional people [ΔE_g in rows (13) and (30)] and paying them wages [ΔW_g in rows (20), (22), and (28)]. At an average annual wage of \$5000, an addition of \$1 billion to the government wage bill will hire .2 million additional employees. To find the multipliers on government wages, therefore, we set $\Delta E_g = .2$. This gives $-.2$ in row (13) and .0258 in row (30) of column P. We also set $\Delta W_g = \$1$ to get 1 in row (20), .111 in (22) and .010 in row (28) of column P. The impact of additional government employment on private GNP is then found by extending

¹¹ To save space some of the less interesting columns of the matrix have been omitted from Table 4. Moreover the tax and transfer equations have been consolidated to show only totals for federal taxes, state and local taxes, and social insurance contributions. If values of any omitted variable are required, they can be calculated from the others. For example, to calculate the federal corporate profits tax yield, use the inverse to calculate ΔP^* and substitute this value in equation (21).

these figures by the weights in the corresponding rows of the GNP column:

$$\begin{aligned}\Delta G^* &= -.2 \times .167 + 1 \times 1.119 - .111 \times 1.119 - .010 \times 1.119 \\ &\quad - .0258 \times 1.119 \\ &= .692\end{aligned}$$

To find the effect of the action on total GNP, we must add in the additional value added by government (i.e. government wages and salaries). Thus:

$$\text{Total GNP} = .692 + 1 = 1.692$$

We also recall that government tax policy can be expressed by shifts in the equations themselves. As shown in Part I, these shift multipliers are equal to the weights found in the row of the inverse matrix that corresponds to the equation being shifted. Thus we see from the -1.119 in row (22) of the GNP column that a \$1 billion shift in the federal personal tax function will reduce private GNP by \$1.1 billion, etc. Note again [row (22) of the federal tax column] that an upward shift of \$1 billion in the federal income tax *schedule* increases federal tax *yield* by only \$622 million due to the decline in personal income and expenditure associated with the rise in taxes.

Some multiplier effects of a selection of government actions are given in Table 5. As before, once the multipliers are worked out they can be combined in any desired proportions. Thus an increase in government purchases of \$2 billion coupled with additional government wages of \$.5 billion and an upward shift of the personal tax schedule of \$1.3 billion would produce a total change in GNP of $(2 \times 1.304) + (.5 \times 1.692) + (1.3 \times -1.119) = \2 billion. The same program would raise total employment by .211 million, and add \$.67 billion to the federal deficit.

D. *A Digression on Deficit Financing*

An interesting and important conclusion to be drawn from Table 5 is that the impact of a government action cannot be measured by merely the existence, or even the size of a surplus or deficit. In the first place it makes a great deal of difference whose deficit is under discussion, and it is not always clear whether deficit "multipliers" are supposed to be applied to the federal deficit or to the consolidated government sector. In what follows we confine ourselves to the latter. In the second place, surpluses and deficits result from courses of action; they are the difference between certain expenditures and receipts. While it is elementary that expenditures promote and taxes retard economic activity, the net

TABLE 5—SELECTED MULTIPLIERS

Multiplicand	Multiplier for Impact on:

^a Additional expenditure of \$1 billion of which half is spent for producers' durable equipment.^b Additional expenditure of \$1 billion in government wages to hire .2 million new workers.

result depends not only on the amounts of expenditures and tax yields, but also on the kinds, and we cannot speak unqualifiedly of a deficit multiplier.

Although this point can be made from purely theoretical considerations [4, pp. 133-55], the econometric model shows the substantial order of magnitudes involved. We see from Table 5, for example, that a \$1 billion consolidated deficit will result from either $\$1 \div .376 = \2.66 billion of federal government purchases or, say a cut of $\$1 \div .462 = \2.16 billion in the federal income tax schedule. Yet the former action raises total GNP by $1.304 \times 2.66 = \$3.47$ billion, while the latter generates an increase of only $1.119 \times \$2.16 = \2.42 billion.

This result can be generalized. According to the multipliers in the last column of Table 5, the consolidated balance (surplus or deficit) is given by

$$\Delta b = - .376\Delta g + .462\Delta a$$

where Δb is the change in the balance and Δa is the shift in the federal income tax schedule. A wide range of combinations of expenditures and taxes will produce the same budgetary balance. In fact, if we set Δb at some fixed value, say $\Delta b = 2$, then

$$2 = - .376\Delta g + .462\Delta a$$

is the equation of an "isobalance" locus. That is, every combination of expenditures and taxation that satisfies this equation produces a \$2 billion increase in consolidated surplus. Three isobalance lines—corresponding to a \$1 billion surplus, a balanced budget and a \$1 billion deficit—are plotted as solid lines in Figure 2.

By the same token, the increase in total GNP is given by:

$$\Delta GNP = 1.304\Delta g - 1.119\Delta a,$$

and if we assign, say $\Delta GNP = 5$, then

$$5 = 1.304\Delta g - 1.119\Delta a$$

is the equation of an "iso-GNP" locus. Three of these are plotted as broken lines in Figure 2.

Inspection of the figure immediately shows that any specified increase in GNP can be attained in association with a wide range of balances and that any deficit or surplus may be associated with a wide range of impacts on GNP. In fact, a government program can simultaneously generate a substantial deficit and a sharp deflation, or a substantial surplus and general expansion. Since transfers, corporate profits taxes, defense orders, and government employment will have still other isobalance and iso-GNP lines, this merely scratches the surface of the possibilities.

FIGURE 2. RELATIONSHIP OF GNP AND DEFICIT TO GOVERNMENT PURCHASES AND LEVEL OF PERSONAL TAXES

E. *Dynamic Responses and Long-Run Multipliers*

As shown in Part I, dynamic responses are studied by iteration. Among the initial impacts of any program, we must find the effects on automobile demand, inventory accumulation, plant and equipment, and other variables whose values re-enter the system with a lag. These form a set of additional knowns for the next year. Using these values, in turn, gives rise to another set, etc. Repeating this operation enables us to follow the implications of a given program over as long a period as desired. It appears, however, that the dynamic elements stabilize by the end of the fifth year, and the system can be treated as in equilibrium after five iterations.

A complete study of the dynamic behavior of each variable in response to each possible policy action cannot be presented here, but Table 6 shows the response of the GNP and its components to a permanent increase of \$1 billion in government expenditure. The tabulated figures are the values of the variables measured as deviations from their levels as of year 0 before the shift in expenditure policy.

In response to increased government expenditure, the GNP rises by \$1.3 billion the first year and under the stimulation of the dynamic factors climbs to a maximum of \$1.6 billion over its initial level. It declines

TABLE 6—DYNAMIC RESPONSES TO A PERMANENT INCREASE OF \$1 BILLION IN GOVERNMENT EXPENDITURE

(Tabulated figures are deviations from initial levels)

	Year				
	1	2	3	4	5
Gross National Product ^a	1.304	1.619	1.582	1.545	1.335
Automobiles and parts	.092	.088	.050	.042	.014
Other Durables	.073	.104	.113	.117	.104
Nondurables	.093	.159	.193	.215	.213
Services	.037	.075	.104	.126	.134
Plant and Equipment	0.	.186	.173	.133	.082
Inventory					
Durable Goods	.048	.079	.017	— .010	— .031
Nondurable Goods	.040	.023	.012	.008	— .002
Net Foreign Investment	— .078	— .101	— .103	— .103	— .098
Government Purchases	1.	1.	1.	1.	1.

^a Detail may not add to total because of rounding.

thereafter under the back-pressure of accumulating stocks. The behavior of the individual components is in keeping with their respective natures. Automobile demand rises immediately to its maximum and declines slowly as the stock of cars on the road accumulates. Consumer expenditure for durables rises sharply and levels off, while outlays on nondurable goods and services continue to rise throughout the period, although at declining rates.

Investment in plant and equipment spurts in response to the immediate improvement in corporate profits and tapers off as the new plant becomes available. Inventory accumulation occurs at a high rate, but durable inventory overshoots and the rate of accumulation is forced somewhat below the year 0 level.

IV. Conclusion

To approximate the behavior of a complex economy by a set of 32 linear approximations is a heroic simplification. Yet experience has shown the statistical model to be a useful and flexible device for economic forecasting. Moreover, while the system of equations is small in relation to the vast structure of pure theory, it is considerably more elaborate than other devices that can be brought to bear on a practical level. Indeed, if an econometric model is nothing else, it is a highly sophisticated method of observing the past operation of the economy and systematizing the information obtained.

Yet, once the technical work of constructing the model is completed, a competent economist needs little more than a knowledge of elementary algebra to understand its nature, or to apply it to a wide range of ana-

lytical problems. Properly used, the model provides quantitative estimates of economic responses to specified changes in conditions. It goes without saying that the accuracy of these estimates is below the level that might be inferred from the precision of their statement in the text. But they show the proper order of magnitude involved and fall well within the practical tolerances required for effective policy evaluation.

WELFARE CRITERIA AND CHANGING TASTES

By RICHARD S. WECKSTEIN*

Conventionally, individual economic welfare depends on individual real income, and changes in economic welfare are evaluated on the assumption that individual tastes remain fixed. The evaluation of well-being when tastes have changed has not been satisfactorily dealt with, and very little is known about the conditions of taste-change. In this paper I deal with those situations in which individual tastes do change, not only as a result of changes in the autonomous cultural determinants of taste, but as a result of ordinary economic activity in which income is gained and used in response to existing tastes.

The assumption that tastes are largely stable over time and between people, is, it seems to me, unwarranted. Consider the following:

1. Utterly implausible contrasts in the conditions of well-being are implied by available real-income measures of welfare in the comparison of people of an industrial society with people of a pre-industrial society. Even though such income comparisons are understood to imply no more than an ordinal standard, or a ranking of societies, it is not at all clear that the Balinese, for example, are so much worse off than the average American that the average of all Europeans and most South Americans can safely be fitted between them on a welfare scale. The customary disclaimer of taste comparability in making international comparisons such as these fails to deal adequately with the difficulty. The trouble is that the Balinese may be *better* off than many groups higher on the real-income scale; this can very well be so even if "well-offness" is confined to economic welfare. For economic welfare is a measure of the degree to which *given tastes* are satisfied by means of scarce resources. I am not concerned here with spiritual qualities, but with tastes which change in some kind of systematic way.

2. The second reason for suspecting that tastes do not stay put is that often the very policies and other reorganizations which produce significant changes in real income are themselves responsible for changes in tastes.¹ For example, the process of planning for a rise in

* The author is assistant professor of economics at Williams College. The first draft of this paper was written while I was a participant in a Ford Foundation Faculty Research Seminar. I have benefited from comments of William Vickrey and Jerome Rothenberg.

¹ It may also work the other way around; that is, new policies designed to produce increases in real income are adopted only after a change in taste has occurred which makes the old level of real income less satisfactory.

income at some given rate in a poor country is quite likely to stimulate the popular appetite.

It is a complicated matter to judge the relative welfare of two such situations. Schoeffler's solution [12, p. 885] to the problem is to attribute equal significance to each of the two taste-states, and, using both, to apply a dual criterion before concluding that an improvement has occurred. If one of the two situations is not preferred to the other under the tastes of *both* situations, no welfare conclusion is possible.

How can it be relevant to use a standard of judgment which is based in part on nonexistent tastes? Moreover, in those, not unlikely, cases in which two taste-states are inconsistent with each other, it is logically impossible for this dual standard to indicate any preference between the two situations. A judgment of "no verdict" of this kind is not simply due to ignorance; it is a positive statement that under the circumstances it is meaningless to make comparisons.²

My proposal for dealing with the problem of the welfare evaluation of income when tastes change is set forth in the following sections. In Section I a new aspiration-welfare concept is introduced. The principal influence to which the aspiration component of welfare is subject and the way aspiration and income interact with each other are discussed in Section II. The distinction between, and the exact nature of, the relation between income and welfare is the subject of Section III. The results of the analysis are then used to develop a critique of income distribution policies in Section IV, and advertising and education policies in Section V. Finally, in Section VI, the effect that experience has on the demand schedule and the welfare interpretation of demand are taken up once again.

I. *The Aspiration-Welfare Function*

In order to avoid the inadequacies of the conventional definition of economic welfare, in which income and economic welfare are loosely synonymous, I propose to assert that economic welfare depends on both real income and the *level of aspiration*³ for real income. The rela-

² I shall return to this question in Section VI below.

³ The idea of an aspiration level of income occurs in Marshall's analysis of saving [8, Bk. iv, Ch. 7 §9] although the term "aspiration" is not used and there is no allowance for aspiration change. Keynes restates Marshall's argument [6, p. 93] in order to cast doubt on any consistent interest-saving relation. The development of a variable aspiration-level concept and its application to the effects of the rate of interest in [13] raises doubts about Marshall's generalization and suggests substitute conclusions. Another application of the concept of economic aspiration in the analysis of the problem of political behavior is due to C. Wolf [14, pp. 296-351]. Wolf's work came to my attention after my own was essentially complete. There are, moreover, important differences between the two concepts in the uses made of the level of aspiration and the influences which affect it.

tion is such that welfare is greater whenever real income rises and whenever the level of aspiration declines.⁴ The aspiration level of income is a more-or-less unrealized level of income which serves as an individual standard and is measured in the same terms as actual income. The steps required to measure aspiration income are however different from those which are taken to measure actual income, but this difference does not prevent us from using the theoretical concepts together. Under ordinary conditions and for most people the level of aspiration for income will exceed real income and real income will be a lower bound to aspiration. Under some circumstances real income might be greater than the level of aspiration, but it is likely that such a situation will be an unstable position of the two values, for either there will be an increase in the aspiration level or real income will simply be allowed to decline.

The situation in which the level of aspiration and real income have equal values provides a kind of universal bench-mark which is given the name Bliss, from which all other states of welfare are measured.⁵ And because there is no special advantage in being better off than you want to be, the only gap between aspiration and income to be considered is the gap between an inspiration level which is high relative to income. The larger is this gap, the further one is from Bliss. Therefore, *ceteris paribus*, the higher the level of aspiration and the lower real income, the lower is economic welfare.⁶

The character of the individual welfare function is represented in

⁴ Let W be economic welfare, A the level of economic aspiration, and E real income, then

$$W = \phi(A, E); \quad \frac{\partial \phi}{\partial A} < 0, \quad \text{and} \quad \frac{\partial \phi}{\partial E} > 0.$$

⁵ In a sense this is an exaggeration, for there are people for whom the values in life are associated with striving activity. For them "the game of life" is the *pursuit* of a goal, not reaching it. Such people are presumably most well off when there is some degree of tension between goals and achievement.

It would be possible to increase the generality of the bench-mark referred to in the text by allowing W to reach a maximum when A and E have a particular relation other than equality. Thus Bliss—if such a term can be used for pursuit-motivated types—is defined as occurring when $A = kE$, $k > 1$, and taking different values for each individual. Such a maximum exists if the partial derivatives of the preceding footnote continue to apply. That is, a maximum exists if pursuit after a more distant goal is not always better than pursuit after a closer one. But it complicates the argument to increase generality in this way. And if my simple definition of welfare fails to satisfy this Knightian criticism it is certainly no weaker on this account than the conventional definition of welfare in which it is not even apparent how to express the tension between aspiration and achievement.

⁶ The simplest expression for this basic idea is: $W = B - K(A - E)$, where B is Bliss and $(A - E) \geq 0$. K is a constant of disutility. An alternate form of the welfare function is $W = B(E/A)^k$, which removes the scale effect, i.e. welfare is taken to be independent of the distance from any absolute magnitude such as subsistence.

Figure 1. The convexity of the function, in this version, is a reflection of the Weber-Fechner law [1, pp. 267-68] which says that uniform

FIGURE 1

increases in the stimulus or source of sensation—in this case the separation of actual income from aspiration income—are accompanied by diminishing increases in painfulness.⁷

The conventional notion of welfare is a special case of the present welfare function, in which aspirations are set rigidly at a high level. In order to make the aspiration-welfare function consistent with the assumption of diminishing marginal utility it would be necessary to draw the curve in Figure 1 concave to the origin. Which way is correct seems to depend on whether to devote attention to the positive pleasure of additional consumption, or to the pain of the lack of it. Perhaps the difference depends on whether individuals measure their state of well-being from a zero income level, in which case it is proper to think of marginal utility as diminishing, or whether individuals measure their condition downward from a bliss point, in which case it seems correct to think instead of a kind of diminishing *dis*utility as the aspiration-income gap widens.⁸

⁷ The welfare expression can be modified, $W = B - (A - E)^m$, where $0 < m < 1$, to conform to this curvilinearity.

⁸ Geometric representation of the alternative form of the welfare function $W = B(E/A)^k$ produces a similarly convex shape. The portion of the curve to the right of the value $(E/A) = 1$

is drawn dotted indicating the special nature of the region. Either W is undefined for $(E/A) \geq 1$ or we can say $E > A$ is redundant and does not raise W above B .

A particular consequence of this definition of welfare which may be disturbing to one's intuition is that it requires Bliss at low-income levels to be as satisfying as Bliss at high-income levels! One who views the condition of the (relatively) poor may find it difficult to believe that people with much less are not in every sense less well-off. I am inclined nevertheless to insist on the conclusion that Bliss is Bliss regardless of the level of income at which it occurs. I have two reasons for doing so. In the first place there is a personal bias that colors one's view of the (relatively) poor which comes from appraising others' incomes against the standard of one's own aspirations. This bias is implicit in many conventional economic-welfare judgments, and it seems to me to be both indefensible and in fact without defenders. This is merely shoddy practice, not doctrine. But, in the second place, if it is true that some of the elements which constitute one's own aspirations are in a sense universal and affect the tastes of the poor, so that it is at least partly appropriate to view the situation of the (relatively) poor through one's own aspiration biases, then Bliss may indeed be *less accessible* to the poor than to the rich. But in that case it is still perfectly plausible and correct to assert that *if* Bliss is achieved at a low income it is equivalent in welfare to Bliss at high income.

It should be clear that the meaning of the level of aspiration is different from both real income and "expected income." The latter may either be considered to be part of real income, or else we may mean by real income some notion such as "permanent income"[3]. Measurement of the level of aspiration will depend on how precisely it is defined operationally. We may approach it either by imagining a set of direct questions and answers designed to obtain the information needed to scale the level of aspiration, or we may replace the level of aspiration by a proxy variable easily measured and which we believe to be a satisfactory index of the level of aspiration. This, however, is a problem to which a solution is not necessary in order to proceed to the matter of the determinants of the level of aspiration.

II. *Determinants of the Level of Aspiration*

A. *Cultural Determinants*

It is ironical that for so important a characteristic of a people as their aspirations the most powerful influences should also be the least accessible to anything like direct control. Taking people in culture groups one with another it is apparent that it is the entire web of their lives from objective family relationships to their attitudes toward themselves which is of greatest importance in setting particular aspiration levels. Thus there is a broad difference in the level of economic aspiration between a Chinese trader in Indonesia and a non-Chinese

Indonesian. Apart from the difference in levels of aspiration between culture groups it is also probably true that individuals in some culture groups are more responsive to the transient influences which are responsible for the shifts in aspiration levels. I shall discuss these influences presently.

It would be a task for an anthropologist to chart the connections between cultures and aspiration characteristics. And it would be immensely worth while to have developed a culture model capable of stating analytic connections between particular aspects of a culture and the sensitivity of aspirations. Without a good deal more knowledge of this kind we will continue to take nations and countries as they are in so far as aspiration motivation goes; and we will have fairly limited ability to affect this set of attitudes, the nature of which is undoubtedly important to their economic development.

B. Turning-Point Experiences

The history of every society includes great events which have given a new start or new direction to the aspirations of its members. Although such historical episodes are often most influential, they are usually outside the conscious control of policy-makers. The Second World War produced many conditions which have proved to be aspiration-stimulating: in the United States, for greater equality and participation in political life by Negroes; in Southern Asia and Africa, for national independence. Aspiration-depressing conditions were widely produced by the severe depression of the 1930's. These events are important in the history of nations, but they are so big and complex that they are not really useful in understanding the mechanism with which we are concerned. For the purpose of understanding the dependence of aspiration levels on events it is useful to consider more limited determinants, especially because these are also controllable.

C. The Communication Media

The spread of literacy is as important in setting aspirations as is any single event, for it brings in its wake a constant flow of printed information about new ways of life which gain prestige and attractiveness when cast in a literary context. In appraising the influences affecting consumer demand, too much attention can be given to paid-for advertising and too little to the informal "advertising" which gives prominence to the material style of life of fictional characters of literature and films. The visual arts, too, have made their impressions on the aristocratic and popular levels of aspiration. Thus the history of art during the Italian Renaissance can be viewed as a colossal adver-

tising campaign for the value of life on earth directed toward people customarily imbued with the value of life hereafter.

D. *Demonstration Effect*

The Duesenberry demonstration effect fits comfortably within the aspiration-level framework if we recognize that it is aspirations for particular income standards which are affected by exposure to examples set by others. We may express this mechanism by relating an individual's level of aspiration to the difference between the mean income of society and the income of the individual. Those whose income is greater than the social mean will, on this account, have a lower level of aspiration, while those below the mean will have a higher aspiration level than they otherwise would.⁹ A strongly class-divided society might require treatment different from a more open society. I shall return to this in Section IV below.

E. *Consumption Effects*

Finally, among the influences acting on aspiration levels is the process of stimulating new wants by satisfying old ones. This phenomenon is given much importance by J. K. Mehta [10, pp. 15-21]. He distinguishes between conscious and unconscious wants, the former being responsible for pain which is relieved in want satisfaction. The latter are only latent wants, and so long as they are not brought to consciousness they produce no pain. But the satisfaction of conscious wants carries with it the satisfaction of related unconscious wants, leading to a kind of net utility gain or consumer's surplus. This is a widespread phenomenon. For example, hunger satisfied by eating rare steak uncovers an unconscious want in particular for rare steak. Initially, eating rare steak does more than merely satisfy hunger and thus makes one better off than before hunger set in. Unfortunately, however, once unconscious wants have been brought to consciousness, they recur, produce pain, and demand recurrent satisfaction. And they are no longer a source of a surplus after their first discovery. Owing to the fact that unconscious wants abound, to seek "salvation" through consumption is in this view a losing proposition.¹⁰ An extreme ex-

⁹ In so far as aspirations are the result of the demonstration effect they can be expressed thus: $A = f(\bar{E} - E_i)$ where E is the economic level; for the i th individual (E_i) and for the arithmetic mean (\bar{E}) of everyone in the society within which social contact occurs.

¹⁰ In aspiration-level terminology this amounts to saying that

$$\frac{dA}{dt} = f\left(\frac{dF}{dt}\right) \text{ and that } \frac{dA}{dt} > \frac{dE}{dt},$$

where A is taken to mean the extent of conscious wants and E the current available economic means of satisfying them.

ample of this phenomenon is learning to smoke, especially marijuana.

Although this conclusion is consistent with the conventional view of endlessly expansible wants, there is some doubt that aspiration levels in fact generally behave in so simple a way. One result of work on the level of aspiration is the discovery that the occurrence of success or of failure to achieve previously set goals is an important determinant of the aspiration level [1, pp. 337-39]. The expansion of wants is not only the result of exposure to goods, it is more the result of discovering that these goods are within reach. As the ability to reach grows, the normal (although not universal) pattern is to set higher goals or levels of aspirations. The difference between this mechanism and the Mehta one is emphasized by the fact that the aspiration shift operates in both directions—levels of aspiration contract in consequence of failure, or declining ability relative to previously set levels of aspiration. A second difference is that new income levels induce adjustments in the level of aspiration toward an equilibrium position instead of inducing an endless expansion of wants.

The level of income is valued in relation to the level of aspiration. A range of income adjacent to the level of aspiration is regarded as a range of successful income in the sense that income in that range represents either a satisfactory approximation to, or satisfactory progress toward the level of aspiration. Below that range, income is regarded as being in a range of failure. Between these two ranges, at the borderline, income is neutral, and the difference between the level of aspiration and that level of income is called the neutral aspiration-income gap, or simply the neutral gap.

Aspiration adjustment responds to the perception of success or failure. The level of aspiration is raised in response to the occurrence of income in the success range; it is lowered in response to income in the failure range, and it remains unchanged in response to the neutral income. The amount of the adjustment is related to the degree of success or failure. In the neighborhood of the neutral income the amount of aspiration shift gradually falls to zero as incomes approach the neutral income from both the success side and the failure side.

Assume a given initial income which is determined by a person's skills and opportunities, and which falls in the range of successful income. Such an income results in the setting of a new, higher level of aspiration in the succeeding period. But with income continuing unchanged this income is then regarded as less successful relative to the new, higher level of aspiration. If the aspiration shift was small so that the given level of income is not below the neutral income level, relative to the new level of aspiration, then again the perception of success induces further rises in the level of aspiration. However, the adjust-

ments diminish and the level of aspiration tends toward an equilibrium value above actual income such that the distance between them is equal to the neutral gap.¹¹

This equilibrium relationship between the level of aspiration and income will normally set aspiration some amount above income. The cases in which the two values coincide probably will be rare. If they do coincide, Bliss is an equilibrium result. In order for this to be the case, however, the aspiration shift must be zero when income and aspiration coincide. For most people Bliss is a disequilibrium point at which the level of aspiration is raised and Bliss is lost.

Equilibrium, in more complicated cases, may be approached by a series of oscillatory movements of the level of aspiration, first rising in response to success so that a given level of income is now in the failure range, then falling so that income is in the success range relative to the level of aspiration. Even this adjustment pattern may lead to equilibrium if the oscillations are damped. But individuals whose pattern of aspiration adjustment is unstable will either grow steadily more disappointed by a sense of failure because of continually increasing aspiration levels, or they will alternately go from failure to success, each time feeling a heightened sense of whichever state they are in at the time.

Unstable cases of these kinds are probably not very important. But it is important to consider another kind of adjustment which has so far been neglected. Until now it has been assumed that income is determined autonomously with respect to the aspiration-shift mechanism. This will not be so in the general run of cases; hence it is necessary to ask how income is changed and what effects such changes produce. An individual's income is not quite fixed by his endowment and the amount of leisure he chooses to give up. To some degree income responds to the effort devoted to creating income. And effort is undoubtedly related to the incentive of a level of aspiration which is high or low relative to income.

The incentive influence of a level of aspiration above income may be responsible for a variety of activities which increase income, such as harder work for longer hours, allocation of income to investment rather than consumption, and a greater willingness to accept reorganizations designed to raise output. The effectiveness of these activities in raising income is likely to fall short of shifts in the level of aspiration. Income adjustment operates simultaneously with the adjustment in the level of

¹¹ The level of aspiration in the current period is:

$$(1) \quad A(t) = A(t-1) + \alpha\{G - [A(t-1) - E(t-1)]\},$$

where G is the value of the neutral aspiration-income gap, and α is the aspiration-adjustment coefficient.

aspiration that occurs in response to success or failure experiences. The opportunity for change in the level of income in response to the incentive of an aspiration-income gap establishes a pattern of steady growth of income; for a persistent gap serves as a constant incentive. The aspiration-adjustment relation which brings aspirations into a neutral relation to income therefore also sets aspiration levels on a path of steady growth.¹² The rate of aspiration growth depends on the strength of both the aspiration-shift and the income-shift, and the size of the neutral aspiration-income gap. The growth rate of income approaches the growth rate of aspirations after an initial time of adjustment. Steady, equal growth of income and aspiration imply neither welfare gain nor loss. However, during early periods, when major adjustments in aspiration and income are taking place, welfare shifts do occur as a consequence of gap values which temporarily diverge from the neutral value.

The importance of the income response in establishing the rate of growth of income and aspirations requires that an effort be made to account for its strength. Although large differences in incentives exist among people, from which much might be learned, the intensity of incentives for any single individual is our only concern here. The strength of the income-increasing effect rises as the incentive of an aspiration-income gap increases, but the relation between these two breaks down and reverses when extended too far.¹³ The reason for this is that aspiration levels greatly in excess of income begin to appear unrealistic and therefore lose their effectiveness. Possible also, high relative aspiration levels are accompanied by severe risk of failure which is avoided by reducing economic effort of all kinds.

¹² The level of income in the current period is:

$$(2) \quad E(t) = E(t-1) + \beta[A(t-1) - E(t-1)],$$

where β is the income adjustment coefficient; its value is assumed to be less than α . Solving equation (1), footnote 11, and equation (2) simultaneously, we get:

$$(3) \quad A(t) = C_1 + C_2(1 - \alpha - \beta)^t + \left(\frac{\alpha\beta}{\alpha + \beta}\right)tG,$$

and

$$(4) \quad E(t) = C_3 - \left(\frac{\alpha}{\alpha + \beta}\right)G + \frac{C_4\beta}{\alpha}(1 - \alpha - \beta)^t + \left(\frac{\alpha\beta}{\alpha + \beta}\right)tG.$$

When t is large the value of A in equation (3) is dominated by the third term, and the value of E in equation (4) is dominated by the fourth term. These identical terms determine the growth path of A and E . While t is still small the adjustment terms—with t exponents—bring A and E into neutral relation to one another. The values of the constant C terms depend on initial values which result from arbitrary external events, so they may be ignored here.

¹³ “. . . there would appear to be a curvilinear relationship between motivational intensity and the efficiency of performance” [9, p. 483].

It is apparent, then, that the strength of the income shift in the course of a long period of time will depend on the size of the aspiration-income gap which tends to persist after initial changes have occurred. This value toward which the gap tends is the neutral value, and hence, finally, we must consider what it is that sets its size. Recall that levels of income which are less than the neutral income are considered to be failures, and the response is a subsequent lowering of aspiration. When income is above neutral income, a success has occurred and this raises aspirations. The size of the neutral aspiration-income gap is critical. If the income-incentive effect is weak due to a small neutral gap, strengthening it requires that the size of the neutral gap be increased, and this requires that a more tolerant view be taken of income performance. A larger range of income must be accepted as successful than had been accepted as successful before. If this is done, the stable gap value toward which adjustments are made will be larger and the incentive aspect of a level of aspiration above income will be greater.

If, however, the incentive effect is small because the neutral aspiration-income gap is very large and serves only to demoralize and dissipate action, the way to achieve more rapid growth is to reduce the size of the neutral gap, bringing it into the range where it serves effectively as an incentive to economic effort. To do this, an individual or society must view more critically the quality of income performance and by so doing restrain the upward adjustment of aspiration which excessive tolerance encouraged.

Thus there are two kinds of stationary, or slow-growth, societies. One of these is the product of small neutral-aspiration-income gaps. In this extreme case a failure to raise aspirations deprives the society of strong incentives. Yet this is a society of high welfare. The other kind of stagnant society is the product of an excessively strong tendency to raise aspirations. As a result the large neutral gap prevents growth and imposes a state of low welfare. The policy implications for the latter societies (and individuals) is to lower their aspirations relative to their income in order both to grow more rapidly and to achieve greater welfare. But the former societies (and individuals) present a more puzzling policy choice, for the achievement of rapid growth must be at the cost of a loss of welfare. And it certainly is not always better to grow than to be well off. This is clear once the mental habit is broken of accepting uncritically the belief that Blissful Communism will be reached at the end of economic development, where abundance guarantees to each all his "needs."

III. *Income and Welfare*

It is so much a matter of habit for economists to equate income

and welfare that it is important to make it clear that they are not the same thing, that they are in fact alternatives for one another. The confusion arises as a result of the common assumption that tastes are constant while income changes, from which it follows that a change in income implies a change in welfare in the same direction. However, the nature of the dependence of income on welfare and welfare on income makes it dangerous always to make this assumption. For, in general to maximize income as a goal implies a sacrifice of welfare. And, ironically, the pursuit of welfare, on the other hand, may require a sacrifice of income.

This is so because efforts directed toward the maximization of income will, to be effective, make use of available means to raise incentives. The manipulation of aspirations to encourage income-increasing efforts may therefore be a required part of the income-maximizing program. If aspirations fail to rise at least as rapidly as incomes, a continuing rise of income is made more difficult by the resulting depression of incentives. Thus there is an opportunity to maximize income (statically) or to raise the income growth rate (dynamically) by allowing welfare to decline. On the other hand, the pursuit of welfare, by holding down the level of aspiration, or its rate of growth, must contribute to a level of income less than a maximum, or to a reduced rate of growth of income. How is this significant?

National policy sometimes must choose between welfare as it pertains to individuals based on the relation between aspiration and income, and other national goals such as national prestige or military security. Although it might formally be possible to subsume both of these national policy objectives in a single social welfare function, to do so serves only to conceal the nature of the choice which must be made. If these goals are kept separate, it is apparent that we are faced with an optimizing problem. In order to simplify the problem I assume that many national goals, other than welfare, are directly related to the level of national income so that we must choose between income and welfare. The choice can be expressed geometrically.

In Figure 2a Bliss lies along the 45° line and income can be controlled along the curved line labeled E -incentive. The theoretical limits to movements along the line are set at the left end by the achievement of Bliss (E_c) and at the right by an upper bound to income (E_m) which can be gained through manipulation of aspiration-level determinants. Practical limits may lie within these limits as a consequence of the difficulties of manipulating aspiration determinants. The increasingly flat slope of the E -incentive curve reflects the weakening stimulus of an increasing aspiration-income gap [9, p. 483]. But

FIGURE 2a

FIGURE 2b

raising income by manipulation of aspiration incentives puts the society at a greater distance from the Bliss line.

This technical relation between aspiration and income may be used to obtain an expression of the relation between income and welfare. In Figure 2a the distance between the E -incentive curve and the Bliss line (measured along a perpendicular to the Bliss line) is a measure of welfare associated with income levels achieved by varying aspirations. The locus of welfare and income combinations is drawn in Figure 2b. It is apparent that they are technical substitutes for each other, i.e., higher incomes (welfare) can be gained by the sacrifice of welfare (income). Moreover, the concave (from below) shape of this possibilities curve is due to the worsening terms on which the exchange of income for welfare proceeds. This is a reflection of the weakening stimulus which larger aspiration-income gaps provide to income and production.

The government's choice between the two goals is made on the basis of its preference map, one contour of which is drawn in Figure 2b. The combination of welfare and income which is optimal for policy-makers with this set of preferences occurs at the point of tangency of the two curves in Figure 2b (W^* , E^*).¹⁴

IV. Distribution of Income

An important issue to which the aspiration-welfare criterion applies is the distribution of income. It is assumed that for each individual the level of aspiration is determined, *inter alia*, by the influence of the income level of everybody else in the society via the demonstration effect.

¹⁴ At (W^* , E^*) the marginal rate of substitution between income and welfare equals the marginal technical rate of transformation between income and welfare.

The presence of relatively rich individuals pulls the level of aspiration of all those below upward, and symmetrically those with lower incomes pull the level of aspiration of those above them down. The strength of the aspiration-shifting influence may be proportional to income differences for the entire range of incomes or it may in some cases follow a square-root rule with extreme incomes losing the intensity of influence as the perception of such extremes grows dim. Another, and possibly more realistic, rule relating income differences and aspiration levels in a class-bound society would discriminate the impact of income differences depending on the class position of the income recipients. Thus, if in a classless society the demonstration effect is expressed as $A_i = f(\bar{E} - E_i)$ for the i th individual (where

$$\frac{df}{d(\bar{E} - E_i)} > 0),$$

then for a class society we may write:

$$A_i = f[a(\bar{E}_\alpha - E_i) + b(\bar{E}_\beta - E_i) + c(\bar{E}_\gamma - E_i) + \dots]$$

where a, b, \dots are weights assigned to the differences for each class, and the subscripts α, β, \dots designate the income averages for each of the corresponding classes. In a class society in which people take their class position very much for granted, the coefficients for the other classes might be small. And in an extreme case hardly anyone might bother to compare himself to the royal family. On the other hand, in societies with pretensions of classlessness the coefficients might be more nearly equal; hence the aspirations of the poorest would be most cruelly raised.

The immediate welfare implication of inequality in the distribution of income on this view of the relationship of members of a society is a neutral one. For it holds that each individual whose income is above average and whose existence serves to raise the aspirations and lower the welfare of those below him, *mutatis mutandis* has his own aspirations lowered and his welfare raised. It matters not at all what the particular pattern of income distribution may be, one distribution has no higher status than another. This conclusion may seem harsh and it may raise our resistance against the arguments which led to it, but it follows from the assumptions that we can add the welfare gains and losses of different members of society with equal weight, and that the influence of demonstration on others' aspirations is symmetrical upwards and downwards. If we deny the first of these assumptions and assert that gains to the poor have greater social value than the corresponding losses of the rich it is easy to avoid the conclusion. However, to attribute a greater value to gains of the low-income receivers is not

justified by any obviously larger aspiration-income gap of such individuals. Unless we hold the view that there is some biologically established minimum to the level of aspirations which keeps the aspiration-income gaps of the poor large, the preference for equality must depend on a social-value rule which establishes the weight of low-income gains above high-income gains (or losses). And we should not be disappointed to discover that the preference for equality is not a consequence of an analysis which omits the relevant value premises. To deny the second assumption, that demonstration works symmetrically, would require a sociological view at odds with much that has been said on the issue by Veblen and his followers. Such a view is likely not to seem the simpler or more natural of the two alternative assumptions.

Suppose now that we are instructed by society to equalize well-being among the members of society, what kind of income distribution is it appropriate to seek? In the short run—or in the situation in which it may be assumed that aspiration levels are constant—it is appropriate to increase the income of those whose marginal benefits from income are greatest at the expense of those with least marginal benefits from income. The benefit from a little more income will be greatest for those whose aspiration-income gap is small. It does not seem justified—assuming aspirations to be fixed—simply to equalize incomes. Over time—allowing for shifts in levels of aspiration as a part of distribution policy—there should be no such welfare restrictions on the policy of redistribution. For social Bliss can be approached by a combination of policies which influence the distribution of aspirations as well as the distribution of income, and what matters is the distribution of the relationship between aspiration and income.

Moreover, aspiration levels respond *inter alia* to changes in incomes and it is therefore inappropriate for social policy to accept as given the distribution of aspirations to which to fit an income distribution. It would be no less satisfactory to attempt to adjust the social distribution of aspirations to suit a given distribution of income. To some degree the spontaneous adjustments of incomes and aspirations of societies achieve a matching of aspirations and income that may, at least in some sufficiently fluid cases, produce a tolerably good arrangement. It has often been observed about able but relatively impecunious individuals that they lack a strong (enough) desire for money. And it is a commonplace that the tastes of the poor are coarse. It is possible in fact that for many of us the objection we have to inequality is precisely that we are offended by a world in which so many have coarse tastes, and it is by raising the incomes of the poor that the tastes of the poor can be elevated. In any event, there is one too many degrees of freedom in the variables to allow an economic definition of the opti-

imum income distribution. When aspiration levels are free to shift, the ideal distribution of income is a matter of social ethics rather than welfare calculus.

V. Advertising and Education

The aspiration-welfare criterion is also relevant to judgments about advertising. Observations of economists about advertising have been directed toward its impact on efficiency in the operation of markets—on the role of advertising in providing information on the one hand and in directing tastes on the other. Advertising, however, enters directly into the determinants of welfare via its influence on the level of aspiration.¹⁵ If advertising did not affect the level of real income we would simply conclude that advertising reduces welfare. But advertising does increase real income by providing consumer information about a wider range of goods and, by subjecting households to temptation of further consumption, provides a heightened incentive to increase their offers to produce. This dual effect makes simple judgments doubtful. Without overlooking this difficulty it is possible, by taking both kinds of influences into account, to define a socially optimal quantity of advertising.¹⁶ This is done in Figure 3 in which the two effects of advertising are described geometrically.

The relation between income and advertising expenditures is shown by an E -function which reveals the potential for increasing income by improving the efficiency of marketing through advertising. As advertising expenditures increase, this potentiality is eventually exhausted and

¹⁵ Thus, $A = f(Ad, \dots)$ where

$$\frac{\partial f}{\partial (Ad)} > 0.$$

¹⁶ $W = \phi(A - E)$ and if $\phi' = \frac{dW}{d(A - E)}$, then $\frac{dW}{d(Ad)} = \frac{\phi'(A - E)}{d(Ad)}$.

But
$$\frac{d(A - E)}{d(Ad)} = \frac{dA}{d(Ad)} - \frac{dE}{d(Ad)},$$

and, if we neglect the influence of E on A ,

$$\frac{dA}{d(Ad)} = \frac{\partial A}{\partial (Ad)}.$$

Allowing for the influence of A on E , however, we write:

$$\frac{dE}{d(Ad)} = \frac{\partial E}{\partial (Ad)} + \frac{\partial E}{\partial A} \frac{dA}{d(Ad)}.$$

Hence the optimum advertising policy is

$$\frac{dW}{d(Ad)} = \phi' \left[\frac{\partial A}{\partial (Ad)} - \frac{\partial E}{\partial (Ad)} + \frac{\partial E}{\partial A} \frac{dA}{d(Ad)} \right] = 0.$$

FIGURE 3

further increases in income are replaced by decreases in income net of advertising expenses. There is therefore an *income*-maximizing advertising budget which is indicated by Ad_y . But this is a value of advertising in excess of the welfare optimum. For, an unavoidable effect of devoting resources to advertising is to raise the levels of aspirations in society. Even if we suppose that aspirations do not rise significantly in response to the rudimentary kinds of informational advertising that may constitute a kind of hard core, the expensive promotional forms of advertising are undoubtedly highly effective in raising aspirations. A general form of this relation is shown in the curve labeled A . The upward-sloping segment may begin farther to the left than I have drawn it, but it is doubtful that the nearly horizontal segment extends as far to the right as the maximum point of the E -function. The *welfare*-maximizing advertising budget (labeled Ad^*) is found where the vertical distance $A-E$ is a minimum, and it is therefore always to the left of the *income*-maximizing advertising budget.

If the motives presented to advertisers by the market are likely to encourage a level of such spending beyond the income maximum (Ad_y), then this amount is *a fortiori* greater than the welfare maximum. There are three circumstances which do indeed lead advertisers to go beyond what is economically justified. They can, first, hope to control the market to give themselves a degree of monopoly by building customer loyalty and raising the barriers to entry. Second, some advertising media are prevented from effectively responding to final consumer preferences because media services are sold only to advertisers as intermediate services instead of to consumers as final goods. This limitation on the marketing of radio and television facilities is in part a technical

limitation, but is also in part a consequence of the method of public regulation of radio and television by the Federal Communications Commission [2]. As a result advertisers buy communication resources for a lower price than would prevail if the market also reflected the direct demand of consumers, and they are thus encouraged to expand advertising beyond the social ideal. Finally, the market uncertainty that firms face is probably met, under conditions of oligopolistic industry, by large defensive advertising expenditures in excess of an income optimum. Therefore, I conclude that advertising in our kind of economy is carried beyond the welfare ideal. Furthermore, even if the motives connected with monopoly or the lure of monopoly were removed and the markets in which the media are sold were reorganized to prevent such uneconomic extension of advertising it would be necessary to find further discouragements to advertising spending if the amounts spent were to approach the welfare ideal.

Suppose now instead of applying this analysis to advertising we consider the question of education policy, most especially in underdeveloped countries where education is such an important determinant of levels of aspiration.

The welfare function remains the same as it was in the advertising case, but we write the aspiration and income functions so as to draw attention to the dual role of education: $A = f(L, \dots)$ and $E = g(A, L, \dots)$, where L equals outlays of individuals and governments on education. Then $W = \phi [f(L, \dots) - g(A, L, \dots)]$. The diagram of Figure 3 serves, changing only the name of the abscissa from advertising to education.

Net income due to investment in education is described by the E -function. The E -function turns down because costs rise and marginal benefits fall. Rising costs are the resultant of two opposing forces. On the one hand costs rise because teachers require specialized training which prevents their easy transfer from other activities. In the long run the flow of teachers can be increased; but because the people drawn into education from other activities will be a relatively high proportion of those in other activities who can be trained to teach, expansion of education requires disproportionate sacrifices of other goods and services to free the needed teachers. Possibly of some additional weight, the marginal teachers in any size educational establishment are likely to be less productive than the average and the quality of education tends to fall as the amount of education increases.

On the other hand, there is some downward pressure on costs as education expands giving rise to economies resulting from a greater division of labor and specialization among teachers and teaching institutions. The greatest gains over time to such specialization come from

the intensified development of the various fields of learning. But, because of the opportunity to countries with education establishments of all sizes for a free flow of ideas and even of people, most of these advantages do not require a large scale of education within any one country. Therefore, on balance, education would appear to expand at increasing cost.

Marginal benefits to education expenditures fall because of the shift in factor proportions. Increasing the numbers of people who are educated in any particular skill means a rise in the growth rate of skills relative to the rise in other cooperating factors, and hence diminishing marginal returns to investment in education. Although it is possible for skilled or educated labor to be underweighted initially, so that for a time there may be increasing marginal returns, this cannot be the case indefinitely.

The effect of education on the level of aspiration is shown by the A -function. The A -function rises as education increases. If the aspiration-raising influence of all education is equally great then the A -function is linear. However, if, as per capita expenditures on education rise, the character of education becomes more modern, less closely related to productive activity, and more of a consumer service, the aspiration-raising influence is likely to increase and the A -function will turn upward more steeply, as I have drawn it.

Education policy based on the calculation of net benefit with respect to fixed tastes is excessive when account is taken of the aspiration-increasing effects of education. The optimal education policy (budget) is at Ad^* (read L^*) which is to the left of the maximum of the E -function, Ad_v .

VI. *Changes in Taste and Demand*

The final point to be made in exploring the implications of the aspiration-welfare criterion has to do with the troublesome question of experience and the demand curve. If experience with new goods "creates" the taste for those goods there is (a) the factual expectation that the observable pattern of purchases as the price falls will not be reproduced in reverse if the price rises [4, pp. 133-34], which is to say that the demand curve is inherently irreversible; and (b) there is no meaning to assertions that one or the other of the two situations—before and after the change in tastes—is the better. Schoeffler's [12, p. 885] strong criterion for judging two such situations is to require that for situation II to be considered preferable to I, II must be preferred to I in accordance with the tastes prevailing at the time of situation II and also with the tastes of the time of situation I. This test is rejected by Rothenberg [11, pp. 887-88] on the ground that, in this kind of change,

learning takes place and therefore the tastes of a later time are the relevant ones, for they are based on the wider experience of both periods.¹⁷ There is an arbitrary concealed value here, a preference for learning regardless of what has been learned.

Taste changes are brought about in the process of aspiration-level shifts. The level of aspiration for total income is the sum of aspirations for particular goods and service components of income, and it is the shifts in the level of aspiration for these components which are ultimately responsible for shifts in the level of aspiration for income in general. Therefore taste changes and aspiration-level shifts are to a large extent the same. (Not all taste changes are aspiration-level shifts, although all aspiration-level shifts are taste changes.) But this view of taste change differs from the view that taste acquisition is a learning process in one important respect. Shifts in the level of aspiration are reversible while learning is not.¹⁸ It is therefore possible for the preference for goods to decline just as well as to increase. Whether there is an aspiration-taste change in conjunction with changes in the consumption of goods must be determined in each case independently of the change in consumption. The evaluation of pairs of situations cannot be made either by a Schoeffler-type double criterion or by resort to the taste standard of the last situation. Each situation is evaluated by its own standard of tastes. And welfare gains can be said to occur when an increase (decrease) in income is greater (less) than the rise (decline) in the standard of taste. Or, to put the same thing more simply, welfare increases whenever the aspiration-income gap is reduced.

¹⁷ Rothenberg nevertheless takes an unjustifiably optimistic view of the problem of irreversibility of demand which he bases on the belief in the formation of basic personality in childhood when fundamental tastes are supposed to be formed.

¹⁸ So at least Rothenberg asserts [11, p. 887], and so it is often stated by other economists. In so far as learning is no more than experiencing, this is probably an acceptable view. A more sophisticated view—and one more suited to use in the theory of consumer choice—would conform more closely to the patterns described by learning psychologists [5, pp. 31, 76-96]. These patterns require more than mere experience for learning to occur; they require some kind of "reinforcement" by reward or punishment, and there is a reverse of the process as well. Extinction of learning occurs with negative reinforcement. Learned tastes can be unlearned just as aspiration-levels rise and fall. Hence the conclusion reached for aspiration-shift taste changes apply also to more generally learned tastes.

A QUARTERLY ECONOMETRIC MODEL FOR THE UNITED KINGDOM

A Review Article

By MARC NERLOVE*

Construction and estimation of a large econometric model is an arduous task which requires a great deal of patience as well as skill. When a new one appears, it behooves us to examine it closely. This article is such an examination of the recently published quarterly econometric model of the economy of the United Kingdom, done by L. R. Klein and three co-workers.¹ This model represents a significant advance in at least two respects:

First, it is the only major econometric model for the current economic structure of the United Kingdom. An earlier investigation by Tinbergen of this structure covered the period 1870-1914, and is thus essentially a statistical essay in economic history [15]. A very small-scale and rudimentary model was done by Radice before the Second World War [14]. In addition to being highly simplified, it, too, has only little relevance to the current situation. In view of the substantial economic difficulties Britain has faced during the post-war era and is likely to continue to face, a detailed econometric model of the sort presented by KBHV is a most welcome addition to the stock of knowledge about the British economy.

The second respect in which the KBHV model represents a significant advance is that it is a quarterly model. Indeed, it is the first substantively serious attempt to develop a quarterly econometric model for any economy.² Earlier attempts by Barger and Klein [1], by Clark [3] and by Gallaway and Smith [6] contain six, seven and four equations respectively. The Barger-Klein model is frankly experimental; the Clark model contains no monetary variables and is highly aggregative so that its significance for policy decisions and forecasting is limited. The Gallaway-Smith model is also excessively aggregative.

*The author is professor of economics at Stanford University. Assistance in the preparation of this article was received under Grant No. G-16114 to Stanford University from the National Science Foundation. Helpful suggestions were made by K. J. Arrow.

¹L. R. Klein, R. J. Ball, A. Hazlewood, and P. Vandome, *An Econometric Model of the United Kingdom*. Oxford: Basil Blackwell, 1961. Pp. xii, 312. 60s. Hereinafter referred to as KBHV.

It is assumed that the reader is familiar with the material contained in Carl Christ's earlier review of the Klein-Goldberger annual model of the U. S. economy [2].

²T. C. Liu is currently developing a detailed quarterly model of the U. S. economy, and it is my understanding that the studies initiated by the Social Science Research Council Committee on Economic Fluctuations will also include the development of such a model. The present article owes much to discussions with Liu concerning his model.

Quarterly econometric models are important to the future of quantitative economics for at least three reasons:

1. In order to estimate and apply an aggregative econometric model, a period must be found over which it can plausibly be assumed that no structural changes have occurred or that those which have occurred are of an exceedingly simple variety.³ Thus, for example, it is difficult to justify fitting a model to data on the interwar and postwar periods combined. Yet if the model is of any degree of complexity, estimation requires substantial numbers of observations; use of annual data thus presupposes rather long periods over which it is implausible to assume that changes in structure have been minor or of a particularly simple sort. A partial solution to this difficulty is the use of quarterly series. Over a ten-year period, for example, 40 quarterly observations are available, so that in the postwar period alone there are more quarterly observations than there are annual observations since 1920, omitting the war years. Nevertheless, it is not correct to say that over a given number of years there is four times as much information in a series of quarterly as in a series of annual observations; to do so would neglect several of the problems discussed in Section II below, most especially the problem of seasonality.

2. Quarterly models are analytically more useful than annual models. In large part, for example, the current debate over the causes of the inflationary tendencies in the U. S. and British economies revolves around the nature of the lags involved. The current pattern of recessions and recoveries in the U. S. economy cannot be well understood in terms of year-to-year changes; its study requires a much finer disaggregation over time. Quarterly models, of course, provide just such a disaggregation over time and are potentially capable of yielding far more accurate information about the structure of lags in the economy than are annual models. Such information is important not only for increased understanding of the way in which the economy functions but for estimation itself.⁴ In addition, the problem of untangling long-run and short-run adjustments, of which observed movements are a complex mixture, is greatly facilitated by disaggregation over time.⁵

³ Such as those which can be represented by a simple shift in the level of one or more of the equations. Several examples of these occur in the KBHV model.

⁴ Some years ago there was a heated debate concerning the relative importance of recursiveness and interdependency in economic behavior. In essence, this is a question of whether most economic variables are simultaneously determined (interdependent) or whether many are primarily determined by the events of a previous period. Since disaggregation over time makes it more likely that a particular endogenous variable depends only on lagged values of other endogenous variables or exogenous variables, such disaggregation makes a recursive structure more plausible. But this gain may be more than offset by increased serial correlation. See Section II below. In the case of a recursive structure, traditional methods of estimation such as least squares are generally appropriate, whereas when the variables are simultaneously determined, more complicated procedures such as limited information methods or two-stage least-squares must be employed.

⁵ The method of distributed lags proposed by Irving Fisher in the 1920's, and recently revived, is potentially very useful in this connection, but it has been shown that use of this method on annual data can lead to seriously distorted results; see [10] [11]. While the use of the quarterly data does not preclude such difficulties, it obviously lessens their severity.

3. Finally, the needs of public and business policy for very short-term forecasts are apparent. If anticyclical policies are to have stabilizing rather than destabilizing effects, up-to-date information on the current state of the economy and of the probable quantitative impact of alternative monetary and fiscal policies is required. A quarterly econometric model, however good it may be, is obviously not sufficient, but it is an important step in the right direction.

I. Structure of the KBHV Model

The KBHV quarterly model consists of 37 equations, of which six are strict identities which hold exactly in every quarter, and one is a quasi-identity based on a stochastic relationship used in the interpolation of one of the endogenous variables. There are thus 30 equations which reflect economic behavior, technological or institutional restraints, or market adjustment processes. The 37 equations determine the values of 37 current endogenous variables as functions of their lagged values and the values of three stock variables and 33 exogenous variables, both current and lagged. The equations and variables which each contains are listed in Table 1 (pp. 158-61).

Design of an econometric model depends on a series of compromises among: (a) the structure of the economy to be described; (b) the multiple, and often partially conflicting, objectives of the model—i.e., is it to be used primarily for forecasting? If so, of what? Is it to be used primarily for policy decisions? If so, of what sort? Or is it to be used to analyze some specific phenomenon such as the wage-price spiral? And (c), the availability of data. The structure of KBHV model reflects all of these factors; it is an unfortunate fact of life that the last of the three tends to dominate.

The first four equations concern the index of industrial production and three of its major components. That four of the key variables in the model relate to industrial production, rather than to GNP and its components, is largely a result of the decision to construct a quarterly model. Only limited amounts of national accounting data were available to the authors at the time they began their study; while they could have interpolated the quarterly series corresponding to the annual national accounts by means of various related series such as industrial production, they preferred to construct their model directly in terms of the major series which might have been used as interpolators. Nevertheless, a good deal of interpolation was necessary, and the problems it raises are discussed below.

Equation (1) explaining aggregate production is the only one of the four which involves more than a single current endogenous variable; it contains a measure of man-hours and total imports, and a simple time trend represents both the growth of the capital stock and technical progress. Use of the trend in this way reflects the lack of quarterly data on the capital stock; even if adequate data had existed, however, the series on capital stock would hardly be distinguishable from trend over such a short period.

The other three production equations relate components of an aggregate production index only to lagged endogenous and exogenous variables. Since engineering, etc., includes a high proportion of capital goods, variables related

to investment decisions, such as the interest rate, are included. Thus (3) takes the place of an investment function and investment never appears explicitly in the model. The interest rate has a small, negative and statistically insignificant effect in this equation. The four production equations, together with the identity (32), determine aggregate industrial production and its three components as functions of three endogenous variables (hours, industrial employment and income) and fourteen predetermined variables. The important point about these four equations is that the link between the production sector, which they represent, and the monetary sector, represented by the interest rate lagged four quarters in (3), is a weak one. Acceleration effects represented by the lagged consumption variables appearing in the equations are substantially more significant, as are the fiscal effects represented by the lagged values of government purchases.

The next four equations are consumption functions for the goods represented in the three component production indices plus a function for the consumption of services. In two of the equations an attempt is made to estimate separate marginal propensities to consume out of wage and salary income and out of property income. A crude form of distributed lag is employed by the inclusion of the value of average consumption in the appropriate category over the past eight quarters. The relative prices of consumption components enter neither the production nor the consumption equations; absolute prices enter only as the deflators of the income variables, and are determined elsewhere in the model by four price-determination equations, (24)-(27), one of which contains a current wage variable. Thus prices are not determined in the commodity markets and they reflect consumption and production decisions only indirectly via the labor and money markets. Had statistics on stocks been available, a closer connection between the real and the monetary sectors might have been established.

In comparison with the U. S. economy, that of the United Kingdom is heavily dependent upon international trade, although less heavily so than some others, such as the Dutch. Both because of this characteristic and because of the authors' interest in the British balance-of-payments position, the international sector is well represented; there are three import equations and no less than six stochastic equations and one identity relating to exports. The three import equations refer to different commodity groups; four of the export equations explain exports to different areas; two of the export equations refer to exports of separate commodity groups, food and engineering (machinery) products; there is no attempt to cross-classify exports by both area of destination and commodity group. All of the equations in this sector contain only one current endogenous variable and may therefore be estimated by least squares. All equations contain lagged variables related to the level of economic activity. Several contain lagged variables reflecting the relevant reserve positions, gold and dollar reserves in the case of U. K. imports, and sterling reserves in the case of exports to the two sterling areas distinguished.

In general, prices play only a small role in these equations; relative prices were significant in the determination of U. K. exports to the dollar area and of food; export prices affect exports to the sterling areas only indirectly through

VARIABLE DESIGNATIONS

A. Current Endogenous VariablesIndustrial Production Series:

P = Total industrial production

 P_f = Production of food, drink, and tobacco P_{eb} = Production of metals, engineering and vehicles, and building P_o = Other industrial productionConsumption Series (at constant prices):^g C_f = Consumption of food, drink, and tobacco C_s = Consumption of services^k C_d = Consumption of durable goods^k C_o = Consumption of other goodsPrice Series:^h p = Price index of total consumption p_f = Price index of food, drink, and tobacco p_s = Price index of services p_d = Price index of consumer durables p_o = Price index of other consumer goods p_k = Price index of fixed assets^k p_x = Price index of total exports p_{xf} = Price index of food, drink and tobacco exports r = Index of debenture yieldsEmployment Series:^h E_l = Total civilian labor force E = Total civil employment E_p = Total industrial employment U = Total unemployment h = Hours worked per week^kWages and Profit Series: w_r = Index of weekly wage rates w_o = Index of weekly wage earnings^k W = Wage and salary income in current prices^k D = Index of gross company profits^kImport Volume Series: I = Total imports I_f = Imports of food, drink and tobacco I_m = Imports of basic materials I_o = Imports of manufacturesExport Volume Series: X_f = Exports of food, drink, and tobacco X_e = Exports of metals and engineering X_o = Other exports X_s = Exports to dollar area, deflatedⁱ X_{er} = Exports to OEEC countries, deflatedⁱ X_{Li} = Exports to independent sterling area, deflatedⁱ X_{Ld} = Exports to dependent sterling area, deflatedⁱB. Stocks^j R = End-of-quarter gold and dollar reserves as a proportion of UK imports S_m = Ratio of stocks of imported materials to value of materials imports in preceding 8 quarters S_d = Ratio of stocks of durable materials at end-of-quarter to production and imports of such in preceding 8 quartersC. Exogenous VariablesDomestic Monetary and Fiscal Series: E_g = Total civilian government employment T_w = Tax rate on income from employment^k T_d = Tax rate on non-employment income^k T_d' = Tax rate on company profits^k T_i = Rate of net indirect taxation^k S_u = Subsidies on food and agriculture^k G_k = Real capital formation by public authorities^k G_s = Real expenditure on current goods and services by public authorities^k M = Average quarterly holdings of liquid assets r_b = The bank rateForeign Price Series: p_1 = Index of all import prices p_{if} = Index of imported food, drink and tobacco prices p_{im} = Index of imported basic materials prices p_{io} = Index of imported manufactures prices p_{met} = Index of imported non-ferrous metals prices^k p_s = Index of domestic prices of manufactured goods in the dollar area p_{wf} = Index of world domestic food prices p_{xo} = Index of export prices of competing countriesForeign Production Series: P_s = Industrial production in the dollar area

(Continued on page 161)

P_{or} = Industrial production in OEEC countries	Shift Variables:
$P_{\xi t}$ = Index of production in the independent sterling area	F = Political factor in wage bargaining = 0 before January 1952 = 1 thereafter
$P_{\xi d}$ = Value of exports of the dependent sterling area deflated by the price index for UK exports	J = Factor for change in status of Northern Rhodesia and Nyasaland = 0 before January 1954 = 1 thereafter
P_{wt} = World production weighted according to share in UK food exports	Z = Food derationing factor = 1 in 1954 and 1955 = 0 all other periods
P_{we} = World production weighted according to share in UK engineering exports	t = Time in units of quarters
Foreign Monetary Series:	Q_1 = 1 in the first quarter = 0 otherwise
$B_{\xi t}$ = End-of-quarter sterling balances in the independent sterling area ^k	Q_2 = 1 in the second quarter = 0 otherwise
$B_{\xi d}$ = End-of-quarter sterling balances in the dependent sterling area ^k	Q_3 = 1 in the third quarter = 0 otherwise

NOTES TO TABLE 1

* Source: KBHV, pp. 51-93.

** Variable dropped in final formulation which was estimated.

^a Equation numbers do not correspond in every case to those used by KBHV due to the grouping employed in this table.

^b Variables have been classified in the form in which they enter the equation. Any variable combination which includes at least one current endogenous variable has been classified as such even though the combination includes one or more lagged endogenous or exogenous variables. This procedure is recommended in H. Chernoff and H. Rubin, "Asymptotic Properties of Limited-Information Estimates under Generalized Conditions," pp. 200-212 in W. C. Hood and T. C. Koopmans, eds., *Studies in Econometric Method* (New York: John Wiley and Sons, 1953).

^c For the reason given in the preceding footnote, variable combinations including lagged but not current endogenous variables and one or more exogenous variables have been classified as lagged endogenous.

^d This is based on an annual empirical relation between the sum of employment income and company profits and the money value of industrial production which was used to interpolate quarterly figures which in turn were used to adjust raw estimates of employment income and of company profits after a seasonal adjustment.

^e In these equations the w 's are weights used to combine component indices into total indices.

^f Exports to countries outside the OEEC area and outside the sterling areas are assumed to be essentially nil and thereby eliminated from consideration in the model.

^g \bar{C} , $^* = f, s, d$, or o , is defined as the arithmetic average of the current and preceding seven quarters.

^h \bar{p} or \bar{U} = arithmetic average of the current and preceding three quarters of p or U , respectively.

ⁱ Deflated by index of the prices of all exports.

^j These are actually endogenous but enter the model in lagged form only.

^k Major interpolation required to obtain this series.

their effects on deflated sterling balances. The latter, however, were found to be quite significant in the determination of exports to these areas. It is unfortunate that the authors were unable to design this sector of the model in such a way that significant conclusions could be drawn regarding the British balance-of-payments position and the controversy concerning the effects of relative prices in international trade. The authors frankly admit that this was not possible because of the restriction of this sector to movements of commodities and neglect of capital movements. Some monetary effects on the international flow of commodities are taken into account through the introduction of lagged reserves. Despite the paucity of information concerning relative price effects yielded by the model, however, the authors devote considerable attention to this matter.⁶ This discussion in the main consists of an extended critique of Orcutt's strictures against the use of regression analysis [13] and an attempt to explain why, despite apparently great efforts, they were unable to uncover significant price effects in all but two of the equations. I suspect that their failure in this direction may have been due to use of arbitrary discrete lags rather than more flexible distributed lags.

A large part of KBHV is devoted to the monetary and labor sectors of the model from which conclusions may be drawn concerning the causes of persistent inflationary pressures in the British economy and possible policy measures for their mitigation.⁷ These sectors are discussed in more detail below; at this point I note only their main characteristics: As already indicated, direct connection between the real and monetary sectors is extremely weak, resting only on a statistically insignificant relation between the interest rate lagged four quarters and the production of metals, machinery vehicles, and buildings. The indirect connection between the real and monetary sectors via the labor market is somewhat stronger, however; it operates primarily through the effects of production upon wages and earnings and the effects of the latter on the general price level; the reverse effects are via the effects of the price level upon wages and the consequent impact upon production. Except for a relatively minor tie between wage and property incomes, which enter the liquidity preference function and depend on employment via identities (31) and (36), and consumption in various categories, the connection is achieved solely through the level of industrial production. This fact makes it especially difficult to focus on whatever purely monetary forces may have operated during the postwar period to produce the inflationary pressures. As a further criticism, since the price levels of component categories are mainly related to the general price level they play virtually no independent role; in many respects, equations (25)-(30) appear to have been chosen solely to close the model.

II. *Special Problems of a Quarterly Model*

In the formulation and estimation of quarterly econometric models, four groups of problems must be squarely faced. These problems are all present

⁶ KBHV, pp. 126-40.

⁷ In addition to pp. 73-86, which deal with the formulation of equations (18)-(30), KBHV devote half of Chapter 4, pp. 111-26, and an Appendix, pp. 260-75, to a discussion of the inflationary mechanism implied by their results. The first half of Chapter 4 was published separately [9].

in the case of annual models but to a significantly lesser degree, and they are often neglected in that context. The problems of special significance in quarterly models are connected with: (1) the interpolation required to obtain many of the series used; (2) the effects of seasonality; (3) the greater degree of serial correlation present in quarterly as compared with annual series; and finally (4) the determination of the appropriate structure of lags to be used. These various problems are, of course, not unrelated.

1. *Interpolation.*⁸ One of the chief difficulties in constructing a quarterly model is the relatively greater problem in obtaining relevant data on a quarterly rather than an annual basis. Given quarterly data, one can always, of course, aggregate them to obtain annual series; the reverse requires interpolation which is considerably more difficult than aggregation. The decision of KBHV to eschew the national accounting framework, because of the difficulty of putting the accounts on a quarterly basis did not entirely free them from problems of interpolation: Of the 73 variables involved in the model, 7 were purely shift variables. Extensive details on the construction of the remaining 66 series are given; 17 of the series required for the model were available only on an annual or semi-annual basis for most of the period.⁹ Thus, more than 25 per cent of the series used were interpolated by KBHV. And, of course, many of the monthly or quarterly series used by KBHV may have been the result of considerable interpolation in the process of official compilation.

In its simplest form, the problem of interpolation may be described as follows: We have a series x_t whose values are known at $t = 0, \Delta t, 2\Delta t, \dots$ and we wish to "fill out" the series at the points $t = 1/2\Delta t, 3/2\Delta t, 5/2\Delta t, \dots$ ¹⁰ There are two basic methods for doing this:

Method I: *Using only the series itself.* Essentially, this is mathematical interpolation. In its simplest form, we interpolate $x_{t+1/2\Delta t}$ along the straight line joining x_t and $x_{t+\Delta t}$,

$$\text{est. } x_{t+1/2\Delta t} = 1/2(x_t + x_{t+\Delta t}),$$

but more complicated methods are possible, which use more than two of the observations to interpolate between each pair.¹¹

⁸ My discussion in this section owes much to an unpublished paper by Milton Friedman, "Notes on the Interpolation of Time Series by Related Series." Regrettably, little attention has been devoted to this subject by economists despite the fact that most economic time series are veritable patch-work quilts.

⁹ KBHV, pp. 141-88. I counted as major interpolation, interpolation of more than eight quarters. Minor interpolation, eight or fewer quarters, was required in three additional cases. It is often jokingly maintained that econometricians spend far more time "manufacturing" their series than they do their models. Joke this may be, but it is not far from the truth. KBHV are to be commended for the systematic airing they have given this particular family skeleton, knowing, as they must have, that to do so would open them to much more effective criticism.

¹⁰ A closely related problem is that of distributing a known total over an interval of time; thus, for example, we know $x_t + x_{t+1/2\Delta t}$ and we wish to find x_t and $x_{t+1/2\Delta t}$ separately. Clearly, we could redefine

$$x'_t = x_t + x_{t+1/2\Delta t}, \quad x'_{t+1/2\Delta t} = x_{t+1/2\Delta t},$$

so that this problem is identical to the simple interpolation problem in x'_t .

¹¹ Logically, one should use all the available observations to interpolate between any

Method II: *Using one or more related series.*¹² Instead of mathematical interpolation, a series related to the one for which interpolation is required, but which is available at shorter time intervals, is frequently used to perform the interpolation. Although there are many ways in which related series have been used for interpolation, all the methods fall into two categories: correlation methods and noncorrelation methods. Let y_t be the related series. A simple example of a noncorrelation method is as follows: Interpolate linearly between the known values of x_t and $x_{t+\Delta t}$ and of y_t and $y_{t+\Delta t}$; use the difference between $y_{t+1/2\Delta}$ and its interpolated value to adjust the interpolated value of x ; thus,

$$\text{est. } x_{t+1/2\Delta t} = \frac{1}{2}(x_t + x_{t+\Delta t}) + [y_{t+1/2\Delta t} - \frac{1}{2}(y_t + y_{t+\Delta t})].$$

A simple example of a correlation method is as follows: Compute the least-squares regression of x_t on y_t for the time points at which both are available; let this regression be $x_t = a + by_t$; then estimate $x_{t+1/2\Delta t}$ from $y_{t+1/2\Delta t}$ according to the regression; thus

$$\text{est } x_{t+1/2\Delta t} = a + by_{t+1/2\Delta t}.$$

Correlation methods probably make more sense than noncorrelation methods in many circumstances.

It is unfortunately not possible to tell from the description given in KBHV precisely what methods of interpolation were employed for each of the 17 series which required it. It appears, however, that about half the series were interpolated using a related series, which itself occasionally required some form of partial interpolation. In other cases noncorrelation methods were used. No seasonal adjustments appear to have been made in the series before interpolation, or allowed for in the interpolation process. This means, in the case of Method I, that seasonality is assumed to be absent and, in the case of Method II, that it is either absent or assumed to be identical in both series. Although it can be shown that, if the correlation between two series is low, use of one to interpolate the other may give significantly poorer results than straightforward mathematical interpolation, KBHV did not justify their use of one method or the other and appear to have used a related series for interpolation whenever it was possible to do so.

The fact that such a substantial number of series required interpolation leads to significant difficulties in the interpretation of the results. First, the interpolation process itself uses up information so that the final results are based on less information than might be supposed by considering the number of observations upon which the estimates are based. Second, interpolation may suppress real seasonality or introduce spurious seasonality. Third, interpola-

pair. It can be shown under fairly general conditions that better and better interpolation between any given pair can be achieved as the number of available observations increases.

¹² I know of no instances when more than one related series has been used, but such methods are certainly possible and could conceivably lead to improved results in much the same way that multiple regression may lead to improvement over simple regression. Again, one should use all of both available series to interpolate between any pair of observations on one of the series.

tion, especially by Method I, may introduce serially correlated errors of measurement in the variables which may contribute to serial correlation in the residuals of the equations to be estimated. Finally, the introduction of such serial correlation may make it much more difficult to determine the appropriate lag structure. Ideally, one should never use any method of interpolation per se, but construct a model using as many series available for the appropriate time intervals as possible, and then use a method of estimation which takes account of the fact that some series are observed only at more widely spaced intervals. Only in this way will it be possible to assess correctly the significance of the results and avoid the difficulties mentioned above. Nonetheless, this ideal is difficult even to approach in practice and KBHV should not be criticized too harshly for having failed to do so perfectly.

2. *Seasonality.* In contrast to annual data, data for shorter time intervals generally contain systematic components not explicable on economic grounds alone. Such variations, called seasonals, are typically removed by more or less complicated methods before the data are used in economic analysis. The following features of methods of seasonal adjustment are relevant to the question of whether seasonally adjusted series should be used in an econometric model:

(1) These methods are generally non-parametric so that it is difficult to determine how much of the information present in the original series remains in the seasonally adjusted series.

(2) Existing techniques may remove more than the seasonal, may not remove all of the seasonal, and may even introduce false cycles in the series of period greater than a year. Existing tests do not enable us to determine what has occurred.¹³

(3) Seasonals have causes, even though such causes may not be entirely economic in nature. Thus, part of seasonal variation, at least, ought to be something explained by the model. Present procedures for seasonal adjustment, however, operate solely on a single series so that they can take no account of the causes of seasonal variation.

In so far as it was possible to do so, seasonally unadjusted series were used in the estimation of the KBHV model.¹⁴ This is in sharp contrast to the two other quarterly econometric models which have been published, the Clark and Barger-Klein models, which use seasonally adjusted data for the most part. Barger and Klein go so far as to say, "It may be urged that the economic subject makes his own (rough) seasonal corrections as he goes along. . . . [Thus] seasonally adjusted rather than unadjusted data appear to be the more accurate measure of the variables that interest us" [1, pp. 420-21]. Thus Klein at least has turned about-face in his attitude toward the use of seasonally adjusted data. Given the state of the art, and especially the fact that most methods of seasonal adjustment are not merely retrospective, I think Klein's present position is the more nearly correct of the two.

Some of the seasonal variation in the endogeneous variables appearing in the KBHV model is explained by the seasonal variation in exogenous variables

¹³ It may be possible to use spectral analysis for this purpose.

¹⁴ The index of profits, D , is an exception.

or by the dynamic structure of the model itself, but not all of it is so explained. What remains is handled by means of three shift variables, Q_1 , Q_2 , and Q_3 . Q_i , $i = 1, 2, 3$, is 1 in the i th quarter and 0 otherwise; in the fourth quarter, $Q_1 = Q_2 = Q_3 = 0$ so that no Q_4 is necessary. It will be noted in Table 1 that except for the strict identities, the Q 's appear in every equation. As the authors remark, this sort of seasonal correction "... implies that the relation ... makes parallel shifts in position from quarter to quarter."¹⁵ While this form of seasonal adjustment is overly simplified, it is easy to estimate and the authors argue its plausibility persuasively. However, the procedure is not without drawbacks since the actual effects of seasonality may be more complicated so that the slopes, as well as the intercepts, of the relations are changed [8]. If this is so, it is comparable to the introduction of errors in the variables, which in turn may lead to estimates with poor qualities and residuals that are serially correlated.

Finally, the seasonal patterns obtained in the equations of the KBHV model are valid only within the context of that model; they cannot be used for general purposes or for analyses not conducted within the framework of the KBHV model. Had a different model been formulated, the estimated effects of the quarterly shift variables might have been quite different.

3. *Serial correlation.* If it is true in economic life that *natura non facit saltum*, then the shorter the time intervals at which economic variables are observed, the more highly correlated will each variable be with its own past values. Since the residuals in the stochastic equations represent the net effects of many small influences which have been omitted, these too will tend to be more highly serially correlated the shorter the interval of observation. Thus serial correlation in the residuals, bothersome enough in annual models and the bane of an econometrician's existence, is really troublesome in quarterly models. Furthermore, until recently very little work had been done on either the effects of serial correlation on the standard estimates of the parameters in simultaneous equations models or what to do about such effects.¹⁶

Despite the serious nature of the problem, KBHV treat it in a rather cavalier fashion. They do not, quite correctly in my opinion, adopt the expedient of taking first differences of all the variables in the model. Such a procedure can, as is well-known, increase the amount of serial dependence. What they do is to fit the model on the assumption that the disturbances are serially independent, then test for autocorrelation in estimated disturbances, using the von Neumann ratio for this purpose.¹⁷ Now this test applies to a given series and not one which has been estimated as a residual. The appropriate test to use in the case of residuals from a least-squares regression is the Durbin-Watson test;¹⁸ Durbin has given a modified form which may be

¹⁵ KBHV, p. 43.

¹⁶ For a recent contribution, however, see A. Zellner [17].

¹⁷ The von Neumann ratio is defined as the ratio of the mean-square successive difference of a series to its variance [7]. A value of this ratio close to 2 will be obtained if the series is serially uncorrelated; a value considerably less than 2 if there is positive serial correlation; and greater than 2 if there is negative serial correlation.

¹⁸ The probabilities for this statistic have been tabulated in [5].

used in testing for serial correlation in systems of simultaneous equations [4]. None of these tests, it should be noted, test for more than first-order serial correlation, i.e., correlation between the current value of a variable and its value lagged one period. Since the kind of serial correlation present, especially that introduced by the interpolation process, may not be of this type, it is dangerous to conclude that a test passed means we are in the clear. But, as a matter of fact, the majority of equations fail to pass the test which KBHV employ.

Although the result would be somewhat modified by the use of a correct test, the serious nature of the problem may be indicated by the test KBHV employed: Values of the von Neumann ratio of 1.4 or less indicate the presence of significant serial correlation in a series of 36 observations at a 95 per cent confidence level. Ratios of 1.4 or less were obtained for the residuals in no less than 20 of the 31 stochastic equations of the model. Furthermore, all but one of the equations for the monetary and labor sectors are in this group, many having ratios as low as one-half.

The consequences of serial correlation in the residuals of a quarterly model are greater than in the case of an annual model, for a quarterly model is more likely to contain lagged endogenous variables. For equations containing lagged endogenous variables, such as (2)-(4) and (9)-(17) in the KBHV model, where ordinarily least-squares would otherwise be appropriate, the estimates obtained in this way are inconsistent.¹⁹ It seems plausible that this result remains true for other methods of estimation appropriate for equations involving current endogenous variables as well.

The presence of serial correlation may be both the result of an incorrect specification of the lag structure and the cause of erroneous statistical results concerning its nature. I have argued the first proposition elsewhere [12], the second follows from the preceding argument. While KBHV cannot be criticized for having failed to employ quite complicated methods of estimation to mitigate the effects of serial correlation, more careful attention to the lag structure might well have reduced the magnitude of the problem.

4. *Lag structure.* Of the 31 stochastic equations in the KBHV model, 15 contain lagged endogenous variables in the final formulation. If we count also those equations in which lagged values enter in combination with a current endogenous variable, the number rises to 19. It is thus apparent that the KBHV model represents a highly dynamic structure. How was this lag structure determined? Except for equation (18), which reflects the outcome of the wage bargaining process, we are given relatively little information on this question.

The lag structure in the wage bargaining equation is justified on institutional grounds; the authors write: "Assuming that wage changes are made for mutually exclusive groups of workers on a twelve-month contractual basis at staggered time points during the calendar year, we should find an average change in wage rates in any particular quarter over the corresponding quarter

¹⁹ See [16]. Consistency is a particularly weak statistical property, so that estimates are pretty bad if they are not consistent. Consistency means essentially that the probability that the estimate differs from the true value tends to zero as the number of observations increases.

of the preceding year to be related to a moving [weighted] average of past price changes and past rates of unemployment. . . . If wage negotiations are evenly spaced . . . the weights will all be equal."²⁰ An additional behavioral lag on the part of unions would result in longer than four-quarter averages but the authors indicate that experiments with alternative lags did not much improve the results.

Except in the case of certain of the labor equations and the four consumption equations, all the lags used are discrete rather than distributed. Thus, for example, the interest rate lagged four quarters enters the production decision equation for metals, machinery, vehicles, and building. Presumably this particular lag reflects the lead of orders over production, but no independent information on the length of this lead-time is given. If lead-times vary considerably for such a diverse mix of products, it can be argued that the interest rate will affect production decisions with a distributed, rather than a discrete lag. If such had been used, it is possible that the effects of changes in the interest rate would have been found to be much greater and a more direct connection might have been established between the real and monetary sectors. The rationale behind the introduction of lagged consumption and exports in the component production-decision equations is that the production decisions depend upon stocks; since figures on stocks are not available, KBHV introduce two of the variables upon which stocks depend. But why have they not introduced lagged production as well, since stocks also depend on this variable?

Distributed lags are used in all four consumption equations. One of the simplest forms of distributed lag models assumes that the effects of past income on consumption decline geometrically as one goes farther back in time; in this case, it is possible to summarize these effects by introducing consumption lagged one period. This is not the form of distributed lag assumed by KBHV; their distributed lag is represented by introducing a lagged eight-quarter, unweighted, moving average of the appropriate consumption variable in each equation. Use of a lagged, eight-quarter, moving average of consumption, however, implies an extremely complicated distributed lag in the effects of incomes on consumption. Furthermore, either form implies that the distributions of lag for wage incomes and property incomes are the same, which seems somewhat implausible. Thus, the approach adopted by KBHV is at one and the same time complex and simplified. Choice of the scheme employed as opposed to the use of a single lagged value of consumption is justified as follows: "If the effect of the distributed lag in income were to be expressed . . . by a lagged consumption term . . . we may find in time periods as short as single quarters that serial correlation in each of the consumption series is so high that it dominates the whole relationship and obscures the influence of other variables. We have tried to avoid this problem by using instead . . . average consumption of the past eight quarters. . . ."²¹

²⁰ KBHV, p. 75.

²¹ KBHV, p. 58. Barger and Klein used the mean value of consumption lagged one and two quarters in their consumption equation and found that this variable dominated; see [1, p. 423]. Nonetheless, they accepted this result as plausible and showed that in the long run the implied income effects were highly significant.

Two points should be made in this connection: First, it is by no means certain that consumption lagged one quarter should not dominate these relationships and that the immediate effects of changes in incomes should be slight. Indeed, the presence of significant positive serial correlation in the calculated residuals of three of the four consumption equations suggests that this may be the case. Second, even if lagged consumption dominates the relationship, this does not mean the *long-run* effects of changes in incomes are slight, only that the effects, whatever they may be, are spread out over a long period of time.

There is no easy answer to the problems of choosing the appropriate lag structure in a quarterly model. The presence of a high degree of autocorrelation in the residuals will make it difficult to avoid attributing more to the lags than they really deserve. One suspects that KBHV experimented with a great many lags before they settled upon the ones they actually used. This is a dangerous, but perhaps unavoidable, procedure. In any case, it would have added a great deal if the details of these analyses had been presented and the actual choices justified by a priori judgment or independent statistical evidence.

III. *Comparison of the KBHV Model with Seven Other Models*

In Table 2 I have compared the KBHV quarterly model for the United Kingdom with six other annual and quarterly models, using for this purpose roughly the same format which Christ used in his earlier discussion of the Klein-Goldberger annual U. S. models [2, p. 390]. The first two panels of the table contain a summary of the two Klein-Goldberger models. The second differs from the first only in the addition of an agricultural sector and the use of two more years for estimation purposes. The third panel summarizes the annual prototype model for the United Kingdom which KBHV developed as a preliminary to their quarterly model. Panels four through six describe Clark's quarterly model, the two Barger-Klein and the Gallaway-Smith quarterly models of the U. S. economy. The final panel presents information on the KBHV quarterly model for the United Kingdom in the same format as for the other six. While Table 2 more or less speaks for itself, there are several points which should be especially noted:

First, the KBHV quarterly model is by far the most disaggregative of the six. Fewer key variables, such as labor force and hours, are exogenous in the KBHV model. As befits the British economy, the international sector is extremely detailed in the KBHV quarterly model, but the prototype annual model is no more detailed than in the Klein-Goldberger U. S. model. All models suffer from a weak monetary sector, and only the Clark model includes inventories as endogenous. Although the instruments of fiscal policy play an important role in both Klein-Goldberger models and the KBHV model, lack of detail in the monetary sector makes the models somewhat ill-adapted for the comparison of alternative monetary and fiscal policies.

Second, the variables appearing in all of the U. S. models appear more "natural," perhaps because we are accustomed to the national accounting framework. As we have seen, eschewal of this framework by KBHV was a deliberate policy to avoid substantial amounts of interpolation. Since their annual model was largely an experimental one used in the formulation of their

TABLE 2—A COMPARISON OF THE KBHV MODEL WITH SIX OTHER ANNUAL AND QUARTERLY MODELS

Model	Years	Stochastic Equations + Identities = Total Equations	Main Endogenous Variables	Main Exogenous Variables	Dynamic Features
Klein-Goldberger Annual U.S. No. 1	1929-41 and 1946-50	14 + 5 = 19	consumption gross investment depreciation imports corporate saving private employees national income and four components general price level general wage level 2 interest rates capital stock 2 liquid asset components corporate surplus	government expenditures 4 components of direct taxes indirect taxes import prices excess reserves 5 population and labor force variables weekly hours	lags of up to 5 years cumulated investment and corporate savings

No. 1	1923-40	3 + 3 = 6	consumption wages and salaries paid by private industry non-wage income net private domestic investment capital stock net national income	government wages and salaries indirect taxes less subsidies government purchases plus net foreign balance	distributed lags in all three stochastic equations first-order autoregressive schemes assumed for residuals in consumption and investment equations ^d purely recursive structure

TABLE 2—*Continued*

Model	Years	Stochastic Equations + Identities = Total Equations	Main Endogenous Variables	Main Exogenous Variables	Dynamic Features
Barger-Klein Quarterly U. S. No. 2	1923-40	3+3=6	same as No. 1	same as No. 1	same as No. 1 except current wage income enters the consumption equation and the residuals in this equation are assumed to be serially uncorrelated
Gallaway-Smith Quarterly U. S.	1948-57	3+1=4	consumption gross investment government expenditures gross national product	money supply taxes	lags of up to two quarters use of first differences
KBHV Quarterly Model for the U. K.	1948-56	31+6=37	industrial production and 4 components 4 categories of consumption general price index and 4 components price of fixed assets export prices interest rate labor force 2 categories of employment hours wages and weekly earnings wage and salary incomes profits total imports and 3 components 4 categories of exports by destination 3 categories of exports by commodity type	import and durable materials stocks gold and dollar reserves government employment government expenditures on current and capital account 4 tax rates money supply bank rate general import price level and 4 components 3 foreign price levels 6 foreign levels of economic activity 2 types of foreign held sterling balances	distributed lags in consumption and wage bargaining equation discrete lags of 1, 2, 3, and 4 quarters

^a Consumption+gross domestic investment in fixed capital+current government expenditures on goods and services.

^b Used to deflate money values of all variables except population.

^c Used to compute "full-employment" GNP.

^d Let u_t be the residual at time t . To assume that u_t obeys a first order autoregressive scheme means that

$$u_t = ru_{t-1} + e_t$$

where e_t is not serially correlated, r is the correlation between u_t and u_{t-1} . The purely recursive structure of this model allows the use of least squares throughout, which in turn makes it possible to estimate a first-order autoregressive scheme in the residuals simultaneously with the structural equations.

quarterly model, KBHV have used aggregates of variables appearing in the latter. An expansion of these models would bring them closer to the national accounting framework and would make it easier to compare the U. K. models with both the annual U. S. models and the detailed quarterly U. S. models which will soon appear.

Finally, the treatment of the problem of serial correlation by Barger and Klein is by far the most sophisticated of all the models compared in Table 2. They have assumed serial correlation in the residuals and in several cases have estimated the correlation of the current value of the residual with its lagged value as part of the process of estimating the parameters of the model. In view of the serious nature of this problem in quarterly models, it is much to

be regretted that KBHV could not employ such a procedure, at least in the estimation of those equations for which least-squares methods would have been appropriate.

Forecasts are a useful way of forming an over-all evaluation of a model, especially if they are not based upon hindsight, i.e., if the data for the forecast were not available when the model was formulated and estimated. KBHV give quite detailed descriptions of the construction of the series which they used, but they do not present any forecasts from the model in the present volume. Since construction of subsequent data according to recipe would be quite difficult for any but the authors, they have, however, been good enough to publish a continuing series of forecasts and post-mortems in another place.^{21a} These form a valuable supplement to their book.

IV. *Some Implications of the KBHV Model for Anti-Inflationary Policy in the United Kingdom*

Because of the way in which the KBHV model is formulated, and because the interest rate was found to be statistically insignificant in the third equation, it is not possible to use the model to analyze the effects of alternative monetary and fiscal policies on the price level. However, under certain reasonable assumptions, it is possible to analyze the effects of direct import controls and wage restraint in a fairly simple manner. To do so will provide an illustration of the way in which an econometric model can be used, and the specific example chosen may be of some interest in connection with current policy discussions in the United Kingdom.²²

The way in which the implications of an econometric model should be deduced may be summarized as follows:

Step 1: Solve the entire model for all the current values of the endogenous variables as functions of (a) their own lagged values, and (b) the values of exogenous variables.

Step 2: The system obtained in Step 1 is a system of difference equations in the endogenous variables of order equal to the greatest lag which occurs. In principle, it is possible to solve this system for the current values of the endogenous variables as functions of (a) time, as measured for an arbitrary origin, $t = 0$, (b) their own initial values at $t = 0$, and (c) current and lagged values of the exogenous variables. Thus the lagged values of the endogenous variables are eliminated.

Step 3: Find the *initial impact* of a change in a policy instrument or some other exogenous variable on any given endogenous variable by differentiating the appropriate equation in the system obtained in Step 1 with respect to that instrument or exogenous variable.

^{21a} See R. J. Ball, A. Hazlewood and L. R. Klein, "Econometric Forecasts for 1959," *Bull. Oxford Inst. Stat.*, Feb. 1959, 21, 3-16; L. R. Klein, A. Hazlewood and P. Vandome, "Re-estimation of the Econometric Model of the U.K., and Forecasts for 1961," *Bull. Oxford Inst. Stat.*, Feb. 1961, 23, 49-66; and A. Hazlewood and P. Vandome, "A Post Mortem on Econometric Forecasts for 1959," *Bull. Oxford Inst. Stat.*, Feb. 1961, 23, 67-81.

²² As this is written, December 8, 1961, it is possible to find lengthy discussions of wage "restraint" in any recent issue of the *Economist*.

Step 4: Use an appropriate equation obtained in Step 2 to trace out the effects over time on an endogenous variable of a permanent or a temporary change in an instrument or exogenous variable.

If the model is fully linear, there are normally no difficulties in carrying out Step 1.²³ Extensive calculations may be involved, however, if the system is large, and the KBHV system is quite large. Furthermore, it is nonlinear, which presents some additional, although not too serious, difficulties. Step 2, however, may be very difficult to carry out in practice and is seldom, if ever, attempted for a model of large size and involving lags of a high order. Consequently, Step 4, which depends on Step 2 is not generally carried out either. In the example, only the initial impact of the policies will be discussed.

In certain models it is not necessary to solve the whole system in order to analyze the effects of certain policies. Imports, for example, are determined solely by lagged values of consumption and exogenous variables by equations (9)-(11) and (33) of the KBHV model. In the present example, I shall suppose they can be directly controlled by the authorities through such measures as direct import controls. If one also assumes that the labor force is given exogenously (which it is not, in fact, in the KBHV model), then the system consisting of equations (1) the industrial production function, (18) the wage-rate determination equation, (19) the wage-rate earnings spread equation, (20) the hours equation, (21) the labor supply function, (22) the supply function for nonindustrial employment, (23) the hours equation, (24) the price over costs mark-up equation, and (37) the labor force identity, are closed on "current account"; that is, these eight equations determine all eight of the endogenous variables they contain in terms of the two we have assumed to be given, labor force and imports, lagged values of other endogenous variables, and exogenous variables. Included in the latter group is a shift variable, F , in the wage-rate determination equation, which represents the wage restraint exercised during the period before 1952 in which a Labor government was in power; F is 0 before 1952 and 1 thereafter. As we shall see, it is not necessary to interpret this variable as measuring restraint, or rather lack of it, per se, but only as determining the unit of measurement, i.e., a set of conditions against which various degrees of restraint can be compared.

If one is to compare the effects of a great number of policies, it is best to carry out Step 1 in full; if, however, as is the case here, one only wishes to compare two, it is easier to differentiate the system or subsystem first, then solve for the appropriate derivative. Suppressing constant terms, quarterly shift variables, lagged values, and irrelevant exogenous variables, the estimates of the eight equations in the subsystem under consideration are as follows:

²³ If each equation is estimated separately, it is conceivable that the resulting system is inconsistent. Separate estimation does not necessarily imply the use of least squares, however. Each equation is estimated separately by limited-information, or Theil's two-stage least-squares, although the fact that the equation is part of a system is allowed for in a limited way. Only full-information methods or the recently developed three-stage least-squares provide true *simultaneous* estimation of simultaneous equations. Limited-information and, where appropriate, least-squares methods were used for the estimation of the KBHV quarterly model. Two-stage least-squares methods were used in the estimation of the annual prototype model.

$$(1) \quad P = .94(hE_p) + .56I$$

$$(18) \quad w_r = - .091U + .85p + 2.90F$$

$$(19) \quad w_g = w_r + 2.06h + .62\left(\frac{P}{hE_p}\right)$$

$$(20) \quad h = .085P$$

$$(21) \quad E_t = - .029U$$

$$(22) \quad E = 1.35E_p - .022U$$

$$(24) \quad p = .42w_g$$

$$(37) \quad U = 18.1E_t - 17.2E$$

It should be noted that in the original, equation (18) expresses the *change* in w_r over its value four quarters ago as a function of an average of current and past unemployment, an average of current and past price level changes, and the shift variable F . Thus, with a constant level of unemployment and a constant price level, wages could be expected to increase 2.9 index points per annum in the absence of such restraint as occurred during the period before 1952 when the Labor Party was in power. The index for w_r is defined so that its average in 1948 is 100. Thus, the unit of "wage restraint" implied is that in the absence of which wages, as measured in this index, would increase by 2.9 points per annum.

Differentiating the system with respect to imports and solving for $\partial p/\partial I$, the derivatives of the price level with respect to the level of the index of import volume, we find

$$\frac{\partial p}{\partial I} = .27$$

when all indices are set equal to 100.²⁴ Differentiating with respect to "wage restraint" and solving for $\partial p/\partial F$, we find

$$\frac{\partial p}{\partial F} = 2.8$$

at values of the indices equal to 100. Thus, a ten point restriction in the index of import volume is roughly equivalent to the type of wage restraint which occurred during the period in which the Labor Party was in power. Without knowing how difficult the one might be to achieve as compared to the other, and without computing the effects of the two alternatives on other important variables in the system, it would be rash to draw any more definitive conclusions as to the appropriate anti-inflationary policy. Furthermore, the above analysis only shows the initial impact of the alternative policies and does not trace out the implications of these policies over time.

²⁴ This step is necessary because of the nonlinearity of some of the equations. The nonlinearity implies that certain derivatives depend on the levels of some of the variables.

The KBHV volume contains relatively little of this type of analysis, perhaps because of space limitations. It would not, however, have required more than three or four additional pages to present the results of Step 1, that is, the current values of the endogenous variables as functions of their own lagged values and the values of the exogenous variables. To have done so would have greatly facilitated the uses of the model for policy purposes and enhanced the value of the book.

V. Conclusions

An Econometric Model of the United Kingdom is an important and interesting book. It is important because it represents the first serious attempt at a large-scale quarterly model and because it concerns the United Kingdom. It is interesting because the British economy is so different from ours in many respects and because the special problems of quarterly models are brought out so nicely in the course of the book.

The chief defect of the model is the lack of detail in the monetary sector and the lack of connection between the real and monetary variables of the model. The authors leave much to be desired in their treatment of the problem of serial correlation, and have omitted a great deal of valuable detail on the process by which they determined the lag structure which was used. Although they have carefully described the construction of the series used to estimate the model, it is not possible to reconstruct the series using only the information provided. Presentation of the model in solved form would also have been desirable, since this would facilitate the drawing of policy conclusions as well as forecasting.

But one cannot have everything. While the authors have provided something which is less than perfect, it is nonetheless of great value.

COMMUNICATIONS

For an Inflation-Proof Economy

"Inflation's evil can even be found in the current recession. Action to fight the decline was inhibited by fear of contributing to inflation in the future. So once again, it is revealed as the enemy of stable growth" [5, p. 1]. This quotation is not unique; indeed the literature on fiscal policy often stresses the difficulties of correct timing, and the dangers of promoting one evil while fighting the opposite one. It follows that the costs of inflation are not limited to undesirable changes in income distribution and in the allocation of resources, but, indirectly, as a result of the very fear of inflation, also include an adverse effect on the level of production itself. Samuelson and Solow estimate that in the United States price stability would involve 7 or 8 per cent unemployment, instead of the 2 or 3 per cent that are unavoidable because of frictions [13]. A. P. Lerner concludes that because of much part-time work and job protection, the reduction of output would be of the order of magnitude of \$30 to \$50 billion at the current level of GNP [7]. This compares with \$35.6 billion, the individual income tax yield in 1958, and with \$26 billion, the budget expenditures of the federal government on international affairs and finance, veterans' services and benefits, agriculture and agricultural resources, national resources, commerce and housing, interest and general government [16]. This cost is obviously in addition to the costs of the inflation that does take place.

Yet this paper is not an additional warning against inflation or an exposition of new anti-inflationary devices. The cumulated knowledge of the mechanism of inflation is, under most circumstances, sufficient for practical purposes of anti-inflationary policy. The common failure of such policies is more often to be ascribed to reluctance due to divided judgments than to ignorance. Rather than suggest new methods for fighting it, the point to be made here is that inflation could, by some institutional arrangements, be deprived of most of its disadvantages.

Definitions of inflation are numerous. Its essence is a rise in prices, but its evils to those who suffer from it and its blessings to those that gain by it would *not* have occurred if *all* prices rose to the same extent. If prices of skilled and unskilled labor rise at the same rate as do prices paid for the supply of capital, both risky and relatively safe, then nothing at all happens to the distribution of incomes. Something does happen, of course, to the value of a unit of money, but, for the moment only, let us disregard that. In practice, some prices are contractually fixed, or at least somewhat rigid, so that relative prices do change when inflation takes place. It is the change in *relative* prices that may impoverish workers, or rentiers, or holders of cash and bank deposits, or pensioners or whoever gets a contractual or semicontractual payment. Needless to say this very impoverishment must have benefited somebody else in governmental or in other sectors.

The allocational effects of inflation, good and/or bad, also depend on changes in relative rather than in absolute prices. Since the rate of return—adjusted for changes in the price level—on savings that are not directly invested by those who save, might become very low during inflation, if positive at all, such savings might decline considerably. This does not necessarily mean that there will be a decline in investment as well; that will depend on the effects of inflation on the distribution of incomes and wealth, on the propensities to consume and to invest, on the rate of real profits, on whether fictitious inflationary profits bring about capital consumption in some industries, and on other factors. In any case, total investment figures might be misleading if some investments are uneconomical, being based on negative interest rates. Because of changes in relative remuneration, and especially because of the rising profitability of speculation, there might also occur undesirable changes in the occupational distribution. Tremendous amounts of energy might be consumed in searches for hedges against inflation, and capital flight abroad may become attractive. This very partial list of the serious costs of inflation indicates, I hope, some awareness on my part of the problems involved. I plead non-guilty in advance to any accusations of a sympathetic approach to inflation, but I do not approve of a passive attitude towards an evil that a lot can be done about. It certainly hurts to see anti-inflationary policies so often ineffective.

Since inflation keeps rearing its ugly head, it is only natural that victims look for protective methods. Such methods include escalating wages and salaries in relation to a price index agreed upon in employment contracts [9], and, for the benefit of unearned incomes, issues of constant-purchasing-power bonds [15] [2] [4]. Arrangements like these are becoming common. Wages have been at least in part automatically escalated in relation to cost-of-living or similar indices in Chile, Denmark, France, Finland, Israel, Italy, Norway, and in some branches of industry in England; in the United States, the use of sliding-scale agreements is limited to a rather small fraction of the working class [1]. The use of constant-purchasing bonds, despite the declared support of W. Stanley Jevons, Alfred Marshall, Irving Fisher, Milton Friedman, Fritz Machlup, Sumner Slichter and many economists in other countries [2, p. 2] is still rather limited. In his survey, Finch mentions the opposition to the idea not only by financial experts, like Otto Niemeyer of the Bank of England, and by business economists, but also by Walter Bagehot in 1875, and by the Treasury and the Council of Economic Advisers in 1952. That the opposition has not subsided is indicated by the rather critical attitude of Robson [11] and Rubner [12] (and for a more unsympathetic attitude, see [14]). Indeed although changes in costs of living are naturally an important factor in wage negotiations wherever they take place, even wage escalations have come under the attack not only by anti-inflation-oriented pressure groups but by economists who object to such devices on the grounds that they start or accelerate a wage-price spiral and thus hurt the unprotected sectors. Naturally the more galloping the inflation, the closer the unprotected sectors get to destruction; and it is a legitimate criticism of plans to protect from inflation specific sectors or groups that the costs

involved might be paid by other inflation victims rather than by the beneficiaries.

Actually the prospects for an acceleration of inflation are not as strong when protection becomes general for then there is less *motivation* to inflate. But in any case, a quicker inflation *mutatis mutandis* does not necessarily imply a worse inflation. Although interpersonal utility comparisons must be made before partial protection plans can be legitimately either condemned or recommended, no such comparisons are needed for a wholehearted endorsement of schemes for a general protection against inflation.

What is suggested here is indeed that, unless explicitly denied in contracts, all contractual payments should be escalated in relation to a price index agreed upon for the purpose. Thus all receivers of wages, salaries, rents, interest, pensions, and other transfer payments—all recipients of income payments that were agreed upon in exact and definitive money units—will be protected from inflation. All that is required is a clause in contracts stating that all money payments explicitly stated relate to a given date, and should be adjusted according to a conversion factor derived from a price index agreed upon. Indeed the experience of many countries indicates that wages, salaries and pensions could be protected from inflation with comparative ease.

But it would not be sufficient to protect income payments only; all payments, including capital payments (both interest and principal) should be submitted to the same kind of escalation. In spite of much criticism, mainly based either on some particularly unfortunate forms of escalation or on attempts of some governments to rig the price index or to evade their obligations in other ways, the experience of other countries does not indicate that constant-purchasing-power bonds are impractical; and under a system where automatic protection from inflation is offered to everybody who wishes it, they lose most disadvantages. Both interest and repayment-values should be escalated, with the market price of bonds, both escalated and nonescalated, and of equities at any particular moment determined by the market.

It is important to include money in this arrangement, for otherwise there will still remain an excise on holding money balances with all its welfare implications. But the compensation of holders of money balances should not be made by means of money creation. It is the decline in the value of real balances that ultimately closes an inflationary gap, so that to increase money balances whenever the price level rose would deprive the system of its equilibrating factor; and the increase in prices, though harmless, might be infinite, so that the economy would regress into the barter stage where, of course, inflation cannot take place. However, this will not take place if the compensation of money-holders is brought about without increasing the nominal value of the money supply. Such compensation in the case of privately-created money should not be very difficult: since bank loans will be escalated, banks may easily guarantee the escalation of the equal amount of bank deposits created by the loans. The nominal increase in bank deposits following an increase in the official price-index will be offset by either decreases in bank deposits or in the amount of money notes outstanding when the loans are

repaid. As to the publicly-created part of money supply, since the whole purpose of the plan is to cancel inflation as a tax, the government should compensate holders of money notes, plus the excess, if any, of bank deposits over bank loans, out of ordinary budget revenues. Technically the escalation of money notes will be much easier if made also through the banking system. If the increase in the price level is considerable, people will protect their money balances by depositing them, even for very short periods, in banks.

For practical purposes changes in the price index for escalation purposes may have to be computed only several times a year or less, unless the inflation is galloping. And although it might appear that galloping inflation is practically assured under the proposed program, especially since many prices, like rent, entering into the computation of the index will themselves be automatically escalated, there are factors working in the other direction: the lack of motivation to inflate if it is realized that nobody is going to win (or lose) by it; and the lack of inflation-induced and inflation-creating increases in the velocity of circulation.

Naturally the more frequent the changes in the "determining" price index the more equitable the system, not only because of the smaller lags between the changes in prices and the compensations for such changes, but because discrete changes in the index create arbitrary differentials between payments before and after an index change. Yet because of aspirations towards practicability it is not suggested that the index be smoothed to a daily trend, or that retroactive adjustments in transactions already closed be made when changes in the index are announced. We hope that the payment structure in the economy will adjust itself to the dates when "official" changes in the index are to be expected with as little ill effects as possible.

All this seems troublesome, and it is. But all the nuisances of the system should be compared with the benefits involved which, tautologically, should be equal to the costs of inflation. How many billions of dollars worth of benefits are sufficient to justify the costs?

The rise of prices in an inflation-proof economy may (though it does not have to) be very high. This price rise, however, is devoid of distributional and allocational effects, and most importantly, recessions in this economy would probably be much briefer and milder; for in this economy no fiscal or monetary measure against recession (which may take only the form of a decline in the rate of growth of production) should be used hesitatingly because of worries lest it overshoot the mark and generate the other evil, inflation. Inflation will have lost its terror.

Is anything wrong with this scheme of sterile or functionless inflation? Opposition to it might often be based on conservatism (in the sense of objection to change), misunderstanding, sheer partisanship, or on intrinsic weaknesses of the scheme. Strongest resistance might come from those who like to condemn inflation but would hate to see it go. That there are sectors in the economy that benefit from inflation is only the mirror image of the distributional effects of inflation, whatever they are. The beneficiaries from inflation consist usually of some profit-receivers and net debtors, and may very well include the government, including the legislative bodies. As is well

known, inflation is a convenient tool to lighten the burden of all domestic obligations that are stated in money terms, like interest payments and redemption of national debt, social security and pension payments, and civil service salaries [10]. Moreover, inflation as a financing device has, at least when mild, some obvious psychological comparative advantages, so that the temptation to use it might, occasionally at least, be almost irresistible. Yet, it is hard to think of a desired effect of inflation that could not be brought about by other premediated policies not necessarily entailing inflation. I do not believe that there are circumstances in which inflation would have no alternatives. Arguments to the contrary almost always depend on some kind of "money illusion" which allows inflation to free from private use resources which would be unavailable otherwise. But if "money-illusionless" economies cannot indeed win wars or get developed, why all the talk of the evils of something which society cannot do without? If society cannot do without inflation, it can hardly be an evil.

Some objections to the scheme might be based on a preference for inflationless rather than inflation-proof economies. But nothing in the scheme prevents strict anti-inflationary policies; it only makes the consequences of a failure of such policies socially much less important.

Resistance might also be based on the inadequacy of any price index for the purpose of general protection against inflation. Ideally, one would have to construct a special index for almost every individual, but that is obviously impossible. The index used should be a general index of prices, like the cost-of-living-index, measuring in some sense changes in the value of money. The index should definitely not be the index of the prices of some specific commodities, including gold or foreign exchange. Some supposedly constant-purchasing-power bonds are escalated in relation to the value of gold or to the exchange rate of some foreign currencies. This seems disadvantageous from many points of view. First, in this case there is indeed some form of "abdication of the local currency" which may be demoralizing. Secondly, escalation in relation to such an index does not at all achieve what is supposedly needed; there does not seem to be much of a moral case for adjusting payments because of devaluations (or appreciations) of the external value of a currency unless there are changes in the internal value as well. Thirdly, since it is unlikely that escalation will depend on exchange rates in some nonofficial markets, and since official exchange rates do not change very often, many problems are created by the greater role played here by the time element. Many inequities may be effected between devaluations; there would be quite a burden on, say, anyone who borrowed shortly before a devaluation takes place, and there would be no help at all for creditors who happen to lend just after a devaluation takes place and are repaid just before one. Fear of such cases might result in nerve-racking speculation and make agreements much more difficult to achieve. Another, and important, reason against the choice of such methods of escalation is that economic conditions might require changing the rate of exchange. It seems silly to try to prevent changes that have to take place in relative prices; yet no devaluation could be effective in a foreign-exchange-escalated system.

Similar objections might be raised against the use of a wage index, suggested by Pedersen of Denmark, for constant-purchasing-power bonds. Pedersen's idea was to assure savers of the constancy of the value of their savings in terms of man-hours of work, thus enabling them to participate in the gains from productivity increases, to force them to share in cuts in available resources, and to contribute to price-stability by having labor realize that any wage increase automatically increases the income of bondholders as well. Such an index, however, cannot be applied generally; certainly it cannot be used to protect wage-earners themselves. Moreover, is it clear that savers should participate in the benefits from rises in productivity as a matter of right? It is quite possible that in some countries such systems of linkage have damaged the very idea of constant-purchasing-power bonds more than any other feature.

It should be made clear, though, that devaluation under an inflation-proof economy will not necessarily be less efficient than in a "normal" economy. The purpose of devaluation is to promote exports and import-substitutes industries; under full employment this may happen only at the expense of industries not directly related to international trade, and such industries will not "permanently" decline unless local demand is cut. Whether a devaluation will achieve a continuing effect under "normal" conditions is an open question, and it will remain so in an inflation-proof economy. If a devaluation is accompanied by a strict monetary policy, the price level would hardly change—although the prices of goods and services not traded internationally would go down. In this case the mechanism for protection against inflation will not operate at all. To the extent that monetary conditions allow some increases in the price level, victims will be compensated, at least partly, by private beneficiaries from inflation, like debtors. To the extent that monetary policy is permissive, and if fiscal policy does not substitute socially approved taxes for the inflation-tax intentionally killed by the scheme, devaluation does not have much chance to be permanently effective. But, depending on the importance of the import component in the commodities and services represented in the escalating index, and on the frequency of adjustments, it might take some time for the original change in relative prices brought about by the devaluation to be completely offset.

Often when the issue is raised it is claimed that since a "general" price index is not under the control of any private borrower, private borrowers could not be expected to link their borrowing to such an index. Since allegedly only a government can issue bonds linked to such an index, the argument would proceed, this is just another scheme to favor the public sector. All that a private borrower can do, it is implied, is to guarantee the value of the loans he gets in terms of the prices of his own products. Bonds linked to the price of particular commodities, like railway tickets, electricity, or cement, exist and may satisfy some specific demands (see [4], [15, pp. 73-76]) but as inflation hedges they are certainly inferior to bonds linked to a general price index. Moreover, producers with liabilities escalated in relation to prices of their own products might tend to maintain prices which are especially rigid. Since every price increase increases proportionally the value of debt, many

firms might often find themselves in an impasse. Price rigidity is certainly not a solution to inflation; neither are bankruptcies. As a matter of fact, when taxes and subsidies are brought into the picture, it is not clear that it always pays for a producer to escalate loan liabilities in relation to the market price of his own products rather than to the general price level. But in any case the borrower is only one party to the transaction, and it is not self-explanatory why his interests should rule. It should not be so difficult for firms to conduct their borrowing as if inflation were not going to take place at all. Changes in the price level change the real terms of contracts; all that is suggested here is to undo the change.

Needless to say the price index chosen for escalation is going to be a tool of great political importance. Changes in this index might make news headlines, for indeed they will be important news for everybody. Pressure groups will do their best to influence the index, and government and Congress certainly have means to change it. It is not at all clear that there is anything wrong with such developments. Surely there is no intention to deprive the government of means to redistribute incomes. The legislative branch remains completely autonomous to decide in what way to finance expenditures. There is no contradiction at all even between an escalated inflation-proof economy and measures imposing taxes on increases in money payments which result from the very escalation. Such taxes, being explicit, reflect a social decision. And the main evil of inflation is not in its distributional effects on incomes and net worths, but in the lack of social-decision backing for such effects.

Since no economy is a closed economy, objections might be based on balance-of-payments arguments. Although it is not obvious that general escalation would necessarily increase the rate of inflation, such a possibility is not ruled out. If this happens, or more exactly if the effect of escalation on the rate of inflation is greater in one economy than in other economies, then adverse developments may indeed follow in the balance of trade of that economy. In the capital-payments sector of the balance of payments there may be actual improvement over a nonescalated case: certainly there is less incentive for capital flights abroad, for they would be worth while only if the rate of devaluation were expected to exceed the internal rate of price increase. Capital flights might still take place, but not any more as hedges against inflation. In spite of this it is not denied that escalation may, in some countries, make devaluations more frequent (and in other countries necessarily more rare). But, apart from considerations of national prestige, devaluation should, in the new setting, cause much less difficulties than in the existing system.

It might be argued—is it not obvious that I am trying to think for possible opponents?—that it would be very difficult to determine the rate of return to be paid on inflation-proof bonds. But like any rate of return, it will be determined by supply and demand.

It may also be argued that purchase of common stocks may be currently used to protect the value of savings against inflation. Even if true, and in many economies in many periods the performance of stocks in this respect has

been far from outstanding, escalated bonds are certainly an improvement, at least for nonspeculative savers. Since inflation-proof bonds are to some extent substitutes to stocks, the demand for stocks will probably be reduced. To the extent that profit-receivers have been benefiting from inflation, escalation would reduce the rate of profits, and thus produce another factor reducing the demand for stocks.

The idea presented here is certainly not original. All that it adds to previous proposals is the suggestion that escalation be general. If I have omitted some basic economic factors, I certainly wish to be told; if on the other hand the factors omitted are not economic but social-psychological if, say, changes in the value of a unit of money are demoralizing even if nobody is economically hurt—then this paper along with most of the economic literature on anti-inflationary policy has been completely misdirected.

Credit Controls and Financial Intermediaries: Comment

A recent article [1] in this *Review* presents some conclusions and arguments on credit controls and financial intermediaries which are open to serious challenge. In particular, the conclusions that (a) the sale of non-marketable government securities to commercial banks is an effective means of increasing control over their liquidity, and (b) reserve requirements have a weaker credit-damping effect on nonbank financial intermediaries than on banks are both, I suggest, misleading if not wrong. Likewise the discussion of reactions by economic units to conditions of excess demand for money and of measures to impair the liquidity of nonbank intermediaries is inadequate and inaccurate.

I. Nonmarketable Government Securities and Commercial Banks

After first surveying the ineffectiveness of various other proposals for controlling commercial bank credit, Alhadeff suggests (p. 658) that, with the exception of short-term securities to serve as liquidity reserves, *only* nonmarketable government securities be sold to banks, thereby preventing activation of idle balances through bank sales of securities. Alhadeff seems unaware of the many pitfalls to such a proposal. First, he underestimates the difficulties in implementation. Second, he ignores some undesirable repercussions, if the proposal could be implemented. Third, his emphasis on long-term securities might be misplaced; for credit control purposes, movements in bank holdings of other maturities are of greater importance than his analysis suggests. Each of these points will be discussed in turn.

Difficulties in Implementation. Selling nonmarketable government securities to banks is likely to prove difficult and costly because bank portfolio practices in general, and special tax considerations in particular, rely heavily on marketability.¹ With respect to bank portfolio practices, Alhadeff argues (p. 657) that nonmarketables would replace "... the potentially troublesome government securities purchased with funds which are temporarily surplus on the customer loan market and which are held for income purposes pend-

¹ "This would preserve for banks most of the advantages of government security holdings . . . fully effective without compulsion on banks to hold government securities. . . . The main disadvantage for individual banks would be the greater inflexibility in portfolio management" [1, p. 658]. Inferentially, Alhadeff's discussion and rejection of other credit control proposals (pp. 656-57) supports the proposition that he considers his proposal very workable and feasible.

ing a revival of loan demand." If, however, long-term securities are as important a source of liquidity as Alhadeff insists, would not banks have to be generously compensated for denying themselves access to this source? Moreover, would not the banks' natural preference (based on good customer relations) for loans rather than securities, the likely availability of other marketable securities, and the not unattractive option, under the circumstances, of waiting for the cyclical upturn, also mean that substantial yield inducements would be needed to persuade banks to hold nonmarketables? Alhadeff faces a fundamental difficulty in stressing the problem of curbing bank liquidity (because this carries with it the implication of heavy and active loan demand even though banks might have temporarily surplus funds) while at the same time asserting that banks are at such a loss for alternative asset acquisition opportunities that they would willingly lock themselves into holdings of nonmarketables. Is there a golden moment when the Treasury can finesse, with little or no yield inducement, banks having temporarily surplus funds into taking an inflexible portfolio position?

The large volume of long-term securities in bank portfolios, furthermore, makes replacement by nonmarketables a task of staggering proportions.² Alhadeff, on the other hand, maintains (p. 658) that such a large volume is favorable to the sale of nonmarketables because it "... suggests that suitable alternative outlets for funds could not readily be discovered." The issue here, pure and simple, is the relative bargaining strength of the Treasury and the banks. In view of the constant and immense new money needs—both refinancing and prospective deficits—of the Treasury, Alhadeff misconstrues, as long as compulsion is ruled out, the balance of power between them. Banks are unlikely to be so desperate for assets as willingly to accept nonmarketables, unless persuaded by yield or compulsion; the Treasury is unlikely to be so persistently affluent or blessed with other sources of funds that it can afford to ignore the commercial banks.³ In short, as long as business cycles retain their postwar moderation, a propitious market climate for placing nonmarketables with commercial banks is unlikely.

Secondly, his proposal overlooks the important tax advantages of security transactions to commercial banks. Banks, like other taxpayers, have the incentive of a preferential rate on income arising out of capital gains from security sales. In addition, however, and unlike other taxpayers, banks are allowed to charge off *net* capital losses against ordinary income without limit. Since the timing of security losses and gains can be controlled to a large extent, banks can gain further by concentrating the realization of each in a particular income year rather than let gains and losses offset each other. The larger tax rates on ordinary income lead to greater tax savings when capital losses are offset against ordinary income rather than against capital

² Flow-of-funds end-year data show that, during the 1950's, bank holdings of government securities of greater than one-year maturity ranged from a low of \$35.2 billion in 1953 to a high of \$52.6 billion in 1955 [9, p. 944].

³ Moderate business cycles will tend to be neutral in their impact on relative bargaining power. In the recessionary periods Alhadeff contemplates, the temporarily surplus position of the banks will be matched by an expanding Treasury deficit; in prosperity, although the Treasury will run a surplus, banks will have plentiful alternatives.

gains.⁴ Periods of falling interest rates are thus generally profit-years; periods of rising interest rates are loss-years.⁵ In this way substantial tax savings are possible in the form of either a preferential rate on capital-gains income or net capital losses reducing ordinary taxable income. These tax considerations are especially relevant to Alhadeff's proposal because, to the extent that tax laws facilitate security sales, they could be appropriately changed to impair liquidity without the need to issue nonmarketables. In the absence of such a change, banks would be giving up a considerable advantage by holding nonmarketables; and this too has yield implications.

Yield Premium and Inflation. The issue of yield must be squarely faced. Alhadeff states (p. 658) that ". . . the absence of legal compulsion to hold these securities would help to raise their yields above the levels that might prevail in a completely captive market and *perhaps* above rates on marketables depending on the availability of suitable alternative outlets for surplus funds" (*italics mine*). All the points raised heretofore suggest, however, that a sharp and certain, rather than a moderate and probable, increase in yield would be necessary to place nonmarketables in bank portfolios. Since banks would not be merely inconvenienced by the switch and because they are in a good bargaining position, substantial yield inducements would be needed, and would have to be progressively higher, the greater the amount it is desired to place. Alhadeff's proposal must be evaluated in this context.

Repercussions of Proposal. Even if Alhadeff's proposal could be implemented, its repercussions on the long-term government securities market would be seriously disturbing. A widespread and well-functioning market for long-term government securities is a major reason why they are so extensively held by so many different kinds of economic units. If banks were to be excluded from holding marketables, this restriction of the market would certainly affect adversely the willingness of others to hold them. The resultant constriction of the market for long-term securities, furthermore, would undoubtedly lead to an increase in the bill issue. Such a development would have the perverse effect of increasing bank liquidity because, as

⁴ "For example, if at the end of 1959 a bank held 2½ per cent Treasury notes maturing in February 1963 that had been acquired at par value when they were issued, the bank could, by selling the securities at the December 31 market price of \$92.875 per \$100 par value, establish a loss of \$7.125 per \$100 par value of the notes it held. So long as the bank's securities losses exceeded its gains, it could deduct the loss from ordinary income. The result would be to lower net income subject to tax at the 52 per cent rate (assuming net taxable income exceeds \$25,000), reducing the bank's tax liability by 52 per cent of amount of losses established. The tax saving would then be available for current investment. . . . However, should the bank have experienced long-term capital gains sufficient to cover its securities losses during the taxable year in question, the loss on the Treasury notes would have to be offset against the gains. . . . Thus while it is always possible for a bank to reduce its current tax liabilities by realizing securities losses, the net tax advantage of recording the loss is considerably greater when it can be deducted from ordinary income, which means that securities losses lead to a greater tax saving if they are established during years in which long-term capital gains are not realized" [4, p. 11].

⁵ For instance, the sum of profits on securities sold or redeemed less losses and charge-offs showed a net loss of \$173 million in 1957, a net profit of \$588 million in 1958, a net loss of \$698 million in 1959, and a net profit of \$110 million in 1960 [6, Table 110, pp. 154-55]. These are net figures for all insured commercial banks, and thus the gains and losses of individual banks are set off against each other.

Alhadeff correctly states (p. 658), "for maximum effectiveness, the supply of Treasury bills would also have to be limited." In this way, depending on how large a constriction of the long-term market takes place, Alhadeff's proposal might be self-defeating.

Proposal Misdirected. Lastly, Alhadeff's proposal may be inadequate because it refers only to longer-term securities; other maturities are dismissed as insignificant for credit control purposes. "Bank holdings of government securities for short-term liquidity reserves are not troublesome for credit policy" (p. 657).⁶ But is not this precisely the reverse order of priority needed? Have not short-term securities provided, by and large, the built-in escape route from stringent monetary policy?⁷ For one thing, bank security portfolios reflect liquidity fears, and certainly the objective of portfolio management is to offset, by appropriate maturity-spacing beforehand, the effects of stringency when it comes. For another, selling short-term securities has advantages for banks: the market is broader, and capital losses (to the extent banks do not desire them for tax purposes) are not a problem. There is no lock-in effect which, under certain circumstances [11, p. 106], could occur with long-term securities. Perhaps Alhadeff was misled in emphasizing long-term security sales because he failed to realize that such market activity may be motivated, as indicated previously, by tax considerations as well as by liquidity reasons:

... a bank that considers the advantages of tax saving obtained by realizing losses on its holdings of Government securities to outweigh the disadvantages of showing the losses on its books may simply sell off its existing holdings and reinvest the proceeds in Government securities. Such 'tax switching' is practiced by a number of banks, but no evidence is available on the extent of this practice [4, pp. 12-13].

II. Reserve Requirements for Nonbank Intermediaries

Alhadeff's views on the familiar proposal of reserve requirements for intermediaries need to be reconsidered in several respects:

1. He assumes (p. 659) that reserve requirements will take the form of demand deposits with commercial banks, and on this basis argues that their impact would be comparatively weak since (a) the credit multiplier would not operate (i.e., there would be no leverage effects),⁸ and (b) intermediaries could always obtain additional reserves by selling assets or increasing their

⁶ There is some ambiguity about Alhadeff's categorization by maturity structure. As a rough approximation, he assumes (p. 657) that short-term liquidity reserves consist solely of Treasury bills and certificates, both of which are required by statute to mature within a year or less from the time of issuance. His other category, to be completely replaced by nonmarketables, consists of "longer-term securities." This leaves, however, the 1-5 year maturities in an anomalous position since it is likely that banks do include at least the short end of their 1-5 year holdings in their liquidity reserves, and rely upon them as liquidity vehicles. Thus, even as a rough approximation, confining the notion of short-term liquidity reserves to only bills and certificates may be misleading.

⁷ The relevance of this point would be enhanced if, as argued in the preceding paragraph, the adoption of Alhadeff's proposal should lead to a narrowing of the market for long-term government security issues.

liabilities to holders of demand deposits. Neither of these consequences would follow, however, if required intermediary reserves took the form of, say, balances at the Federal Home Loan Banks.⁸ This would permit a multiple impact on the total supply of intermediary credit through changes in reserve requirements, and would make additional reserves obtainable only at the discretion of the central banking institution. Alhadeff's case rests on a particular institutional form which in itself is not strictly comparable with the operations of the Federal Reserve System.

2. Even if Alhadeff's assumption as to reserves is accepted, a question as to the relevance of his argument arises. He contrasts the comparatively strong impact of an increase in reserve requirements on the credit volume of commercial banks with its weak impact on intermediary credit extension. He argues (p. 660) that "the difference exists because following an increase in reserve requirements, intermediaries could increase the volume of intermediary reserves whereas the banking system could not increase the volume of bank reserves." Yet is not credit extension the fundamental issue rather than the volume of reserves? Alhadeff seeks to justify his emphasis on reserves by abstracting from velocity effects. "In view of these possibilities [i.e., velocity changes] . . . the actual variation in the volume of credit corresponding to different assumptions about changes in reserves may only approximate the variations in credit-granting activities" (p. 659). how

Velocity, though, is the essence of the problem: no matter how credit is extended, are intermediaries or banks, in the circumstances Alhadeff postulates, in a better position to do it? True, intermediary reserves are likely to be increased since intermediaries extend credit mostly through attracting current savings flows whereas banks can extend credit only through idle balance activation by asset sales; but how relevant is this consideration? The real question is empirical: which way offers the greater scope for credit extension—selling old assets to holders of idle balances or attracting the current flow of savings? On the one hand, idle balances are likely to be held by large holders, sensitive to changes in financial asset prices; on the other hand, the current flow of personal savings is likely to be spread more widely in smaller amounts, and to gravitate toward thrift intermediaries. Likewise, commercial banks tend to be more active in portfolio switches, whereas intermediaries tend to maintain their holdings, are more limited in their range of financial assets, and depend upon repayment flows and their success in attracting current savings for portfolio readjustments. Moreover, commercial bank portfolios have shorter maturity structures which also facilitates switching.

For all of these reasons, then, credit extension, as long as the stock of idle balances is large, will take place largely through bank asset switches. As the stock of idle balances diminishes, then the flow of current savings, presumably going mostly to thrift intermediaries, will become more important. Thus the contrasting impact on credit extension which Alhadeff draws depends upon

⁸ Savings and loan associations already hold considerable balances in this form, and threaten to increase these deposits at the expense of their demand deposits at commercial banks as part of their counterattack against commercial bank efforts to alter the tax status of mutual institutions.

the absence of substantial idle balances. If, empirically, idle balance activation is initially likely to be more important, as I suggest, then the weaker impact of increased reserve requirements on intermediaries will not be very relevant. Increased reserve requirements will be unavailing for both banks and intermediaries alike.

3. Finally, Alhadeff neglects to mention that reserve requirements might affect intermediary credit extension through a reduction in earning capacity. If they are forced to hold increased reserves, the reduction in earning assets will impair their ability to attract current savings flows by putting pressure on the rates they can pay. In this way reserve requirements may restrict intermediary deposit growth, and thereby credit extension.

III. *Reactions to Excess Demand for Money*

Alhadeff argues (pp. 662-63) that the public will not significantly shift, during periods of restrictive credit policy and rising interest rates, from money balances to intermediary deposits. Although this is likely to be so, it will hardly be true for the reasons suggested. He implies that holders of money balances may be more attracted to other liquid assets, specifically Treasury bills, because of greater yield; or they may retain their demand deposits because of higher compensating balance requirements or higher service charges.⁹ Surely there is misplaced emphasis here; as argued earlier, intermediary deposits stem largely from households, and not from asset-shifting by holders of large idle balances. Both because households do not generally hold large cash balances and because other holders of idle balances are not greatly interested *at any time* in savings deposits, shifts from money balances to intermediary deposits are not likely to be caused by an increase in the opportunity cost of holding cash balances.¹⁰ Compensating balance requirements, rates on short-term money market instruments, and perhaps service charges are thus not relevant matters since they have little impact on small savers. Indeed at a later point (p. 670), Alhadeff remarks: "To a very great extent, the intermediary deposits accounts are held by small savers who are not accustomed to buying marketable government securities."

Alhadeff also attempts (pp. 664-65) to minimize the extent to which the public will shift among nonmonetary financial assets, more specifically from commercial bank savings deposits to deposits with other intermediaries. In doing so, he underestimates the importance of interest rate differentials in determining the placement of thrift deposits. "Deposit placement as between institutions is a function of many variables . . . and the interest rate is only

⁹ Compensating balance requirements, however, can take the form of time deposits. The banks gain the advantage of lower reserve requirements, and usually the time deposit is noninterest-bearing in such cases. The borrower gets the advantage of obtaining a negotiable instrument, a time certificate of deposit, which may be discounted to obtain additional funds. See [7, p. 122] [5, p. 66].

¹⁰ The latest survey of demand deposit ownership shows that, as of January 25, 1961, the personal deposits of individuals were 29.7 per cent of total demand deposits in insured commercial banks [10, p. 405]. A previous survey [8, p. 380] showed that roughly half of all personal deposits of individuals are in accounts of less than \$5,000.

one of these" (p. 664).¹¹ His point that *relative* interest rate differentials (ratios of effective interest rates paid on savings deposits) have moved sharply against nonbank intermediaries is of little relevance in measuring responsiveness to changing rate differentials, since absolute differentials are more likely to be influential in savings decisions by households. Though these have recently narrowed somewhat, they remain greater than one per cent for savings and loan associations, and slightly less for mutual savings banks.¹² Even more importantly, the *persistence* of a differential (absolute or relative) is likely to be of greater significance than its size. One should not believe in instantaneous causation in these matters; commercial banks had the advantage of being the more familiar and widespread financial institution, and time was needed to gain public recognition and acceptance of the nonbank financial intermediaries. Thus the slower growth in commercial bank savings deposits (and we must eliminate commercial bank time deposits, which have grown more rapidly, in this comparison because they are held largely for nonthrift reasons) is part of a cumulative process in which rate advantages, although narrowing, become more important over time as the public realizes that, in other significant respects, e.g., safety, liquidity, convenience, banks and deposit intermediaries are substantially alike.¹³

This persistent but narrowing interest-rate spread over time is compatible with Alhadeff's point (p. 665) that "... a tight money policy may not widen interest rate differences very much among savings deposit institutions." Indeed, I would go even further than Alhadeff. Banks feel the pinch of tight money more severely. Their reserves are controlled, and as a tight money policy continues, it becomes increasingly difficult to activate idle balances. Savings inflows thus become more important for banks, and they are therefore more likely, subject to limits imposed by Regulation Q, to engage in active rate (and other forms of) competition at such times. When they have surplus funds, they are not very keen about fighting for savings deposits.¹⁴ Deposit intermediaries, on the other hand, depend exclusively on savings flows for portfolio growth, and therefore must cultivate this flow during periods of monetary ease as well. Thus one would expect differentials to narrow during periods of tight money. The continuing gains of savings and loan associations

¹¹ Cf. also n. 10, p. 665 and a previous article, jointly authored by Alhadeff and cited at this point, in which it is maintained that "... the interest rate difference is discredited as the explanation for the relative decline of commercial bank savings" [2, p. 5].

¹² Between 1946 and 1959, the absolute differential between savings and loan associations and commercial banks has ranged from a high of 1.7 per cent in 1953 to a low of 1.2 per cent in 1957. Between mutual savings banks and commercial banks, it has ranged from a high of 1.4 per cent in 1953 to a low of .8 per cent in 1947 and 1959 [12, p. 21].

¹³ This argument applies with much greater force for savings and loan associations than for mutual savings banks because, on the surface, institutional differences seem greater between the former and commercial banks.

¹⁴ "... commercial banks, as an industry—and there are many exceptions—are not too much interested in savings accounts as a steady diet. When they need the money because loan demand is heavy and interest rates are high, they go after savings; when there is a surplus of funds seeking investment, they lose the desire for savings accounts" [3, p. 153].

during such periods despite this (both relative and absolute) narrowing favors my hypothesis about the cumulative impact over time of rate differences.

Alhadeff's discussion (p. 667) of what he terms the availability effect—shifts from savings deposits to demand deposits—also suffers from his failure to distinguish correctly who holds savings deposits. Economic units holding savings deposits are not likely to want to hold increased cash balances. Why should they, when savings deposits provide them with liquidity plus a return on their funds? The high turnover rates on thrift deposits and the high ratio of withdrawals to deposits would seem to substantiate this point. Alhadeff seems to have in mind a liquidity scramble by business holders of commercial bank time deposits. Since by law commercial bank savings deposits are restricted to individuals and nonprofit institutions, and since businesses hold negligible amounts of intermediary deposits, the availability effect is unimportant for savings deposits.

IV. Credit Control and Deposit Intermediaries

In a concluding section on restricting intermediary credit, Alhadeff discusses (pp. 668-70) various possibilities for impairing the liquidity of deposit intermediaries by reducing the volume of intermediaries' reserves available for credit extension.

In dismissing the idea of a uniform ceiling rate imposed on the different thrift institutions to equalize competition and thus reduce intermediary reserves (or retard their growth), Alhadeff argues (p. 669) as follows:

... a ceiling rate set at the same level as the ceiling on time deposit rates would simply permit more intensive product competition by those institutions which now pay more than the ceiling rate. Product competition could then substitute for rate competition and could undermine the attempt to extend the impact of an excess demand for money to the intermediaries. The alternative, which is to set the uniform rate ceiling at the highest level of rates paid by any of the savings deposit institutions, would be ineffective because it would leave existing rate competition unchanged.

I contend, however, that the competitive position of commercial banks is likely to be improved in either case. The scope for product competition by nonbank intermediaries is considerably more restricted than Alhadeff implies; and, as argued above, rate differentials have been the important mainspring for intermediary growth. In a sense, the differential measures the nonprice advantages of commercial banks. Thus a ceiling for all set at the same level as the ceiling on time deposit rates would mean an enormous improvement in the competitive position of commercial banks. Likewise, a uniform ceiling set at a higher level, by permitting banks to pay higher rates *if they wish* (and some have so indicated), would of necessity alter existing rate competition to the advantage of banks.^{14a}

^{14a} This comment was completed prior to the recent upward revision in permissible interest rates that commercial banks may pay on time and savings deposits.

Alhadeff concludes by suggesting that putting pressure on the public's liquidity would encourage a shift toward securities and demand deposits, and away from intermediary deposits, thereby reducing intermediary reserves. With respect to a shift towards demand deposits, we merely repeat that in view of how intermediary deposits are distributed, it is extremely unlikely that such a shift could be induced. With respect to a shift towards securities, his objective is puzzling. Although intermediary reserves might be restricted, the volume of credit would be unchanged. What is to be gained by a switch from indirect to direct credit extension?¹⁵ This makes sense only if Alhadeff is assuming that the shift would be to government securities which would have otherwise been taken up only by virtue of the monetary authorities allowing a sufficient expansion of the money supply to enable banks to hold that additional amount. In this restricted sense, limiting intermediary growth would result in less total credit being supplied than if the government financed itself through the commercial banks. Alhadeff's mention of the "Magic Fives" in this context (p. 670) indicates that such an interpretation may be appropriate. As he suggests, however, resort by the government to bidding away funds from deposit intermediaries raises many problems, particularly with respect to the status of the savings bond campaign, and the anomaly of competing with thrift institutions on the one hand, and helping them on the other by insuring the safety of deposits.

V. A Concluding Observation

Is there not something inherently deceptive and illusory in viewing the problem of credit control as that of finding some novel control technique to place in the hands of our financial authorities? While innovation in forms of control is of undoubted importance, lack of imagination and fertility in devising new credit control schemes has not, on the whole, been the major stumbling block. The difficulty lies, rather, in the inadequacy of our regulatory structure. Financial regulation is of two broad types: we regulate for purposes of economic stabilization and for purposes of guaranteeing the safety, solvency, honesty, and social responsibility of our financial institutions. Only the commercial banks, however, are explicitly regulated on the former basis. And therein lies our dilemma. On the one hand, considerations of equity and the likelihood that other financial institutions will successfully offset its impact preclude the pursuit of monetary policy *à outrance*; on the other hand, we have no economic stabilization-type controls to apply to nonbank financial institutions. No proliferation of *ad hoc* control devices will resolve this di-

¹⁵ The point at issue is how pressure on the public's liquidity affects credit through its impact on intermediary reserves. I am abstracting, as does Alhadeff, from the restrictive credit impact attributable to the reduction in the public's liquidity because of shifting from intermediary deposits to securities. In this connection, however, would not great increases in security yields be needed to persuade the public to react to pressure on its liquidity by becoming even more illiquid? Furthermore, Alhadeff ignores what would be the most likely way of retarding the growth of intermediary reserves as a result of illiquidity: namely, the use of savings deposits to finance current consumption. Perhaps this omission is due to the deliberate exclusion (n. 8, p. 662) from his analysis of the effect of possible changes in expenditure on output.

lemma. More drastic and fundamental regulatory reforms, involving the financial structure as a whole, are likely to be needed.

Credit Controls and Financial Intermediaries: Reply

I welcome this opportunity to amplify the points which Rozen has raised about my paper and to demonstrate that his detailed criticisms have failed to damage either my analysis or my conclusions. I will also show that his criticisms contain serious analytical errors and errors of interpretation.

I. Nonmarketable Government Securities and Commercial Banks

My purpose in this paper was to suggest a relevant and, I hoped, a fruitful line of inquiry and not to lay down final policy judgments in this area. In order to illustrate what I meant by a structural change in lieu of additional controls, I briefly sketched the nonmarketables idea in the first section of my paper. The nonmarketables idea is not the only example of a possible structural change; indeed, another was proposed by Rozen, viz., to eliminate the tax advantage which now facilitates security sales by banks. Any plan to increase the effectiveness of credit policy is going to raise some problems. This reply is not the place to settle whether the nonmarketables or some other

idea (or combination) is the best structural change we can make. That can only be settled by a detailed investigation of the possible alternatives and, in my replies to Rozen's specific objections to the nonmarketables, I do not mean to prejudge the outcome of such an investigation. I will show, however, that Rozen has seriously exaggerated the problems associated with the nonmarketables.

Difficulties of Implementation. Rozen's analysis of the difficulties of implementation is inadequate because he ignores many important facts which would work against his conclusion. First, he underrates the alternatives available to the Treasury by ignoring the possibility of increasing the level of Treasury securities in the portfolios of the Federal Reserve.¹ Second, he overstates the importance to commercial banks of the tax advantage on government securities. Although we need to know more about this matter, one study in the Tenth Federal Reserve District concluded that "... most banks either were unaware of the advantages of establishing tax losses or did not consider them desirable ..."[6, p. 175]. Third, he neglects to mention that banks must hold a substantial amount of government securities as pledges for various purposes, including those required to secure government and trust deposits [12, p. 44]. Fourth, he does not recognize that government securities perform an important role in enhancing the safety of banks. No other earning asset can provide a comparable degree of safety. If a bank did not hold government securities, the supervisory authorities (as well as the bank's management) would undoubtedly insist on a sharp increase in the bank's capital. This would seriously impair stockholder profitability which depends heavily on the leverage provided by a thin equity ratio. ✓

Rozen has strongly overstated the difficulties of implementation because he has not really faced up to the question of whether suitable alternatives exist. In recent years, commercial banks have held the enormous volume of about \$40 billion of marketable government securities with a maturity of one year or more [9, p. 449]. That is why I said that "The present volume of government securities in bank portfolios suggests that suitable alternative outlets for funds could not readily be discovered" [1, p. 658, n. 2]. Under the circumstances, Rozen is not at all convincing when he tries to establish the existence of alternatives merely by *asserting* "the likely availability of other marketable securities" or the "not unattractive option" of holding excess reserves pending the revival of loan demand (p. 186). Moreover, I suggest that it probably would not be attractive to hold idle funds even if other marketable securities could not be found. A banker would have to balance the net income from holding idle funds and then lending them during the cyclical revival against the income that could be earned by investing them in nonmarketables for the entire period. After making this analysis, most bankers, even in the absence of a substantial yield premium, probably would decide not to hold a large volume of idle funds during the slack period. First, government securities provide an important amount of income for banks² and it may not be possible to forego that income ✓

¹ A secular increase has been urged on other grounds in [20, p. 43].

² For example, in 1960, earnings on U.S. government securities as a percentage of total earnings ranged between 15.5 and 26.9 per cent for different size groups of member banks [10, p. 613].

during the slack loan period. Second, even if an individual banker were willing to tolerate short-run operating losses in the interests of a possibly larger return in the long run, he would realize that the losses would disturb the supervisory authorities and probably provoke administrative penalties, restrictions, or even reorganization. Third, it is more expensive for a bank to make loans than to buy government securities. This reduces the expected net return on the future loans and thereby reduces the attractiveness of holding idle funds. Fourth, whereas the income from investing in nonmarketables is certain, the income from holding idle funds and eventually lending is not, and this uncertainty would also reduce the attractiveness of holding idle funds.

Yield Premium and Inflation. I have already stated [1, p. 658, n. 2] that a yield premium may be necessary to put the nonmarketables into effect. But a higher interest cost to the Treasury would not be sufficient to disqualify an anti-inflation scheme, not even if Rozen could prove that the premium would be "sharp and certain." This is an old issue in monetary economics and, at the time of the Federal Reserve-Treasury accord of 1951, it was widely recognized that:

the advantages of avoiding inflation are so great and . . . a restrictive monetary policy can contribute so much to this . . . that the freedom of the Federal Reserve to restrict credit and raise interest rates for general stabilization purposes should be restored even if the cost should prove to be a significant increase in service charges on the Federal debt and a greater inconvenience to the Treasury in its sale of securities for new financing and refunding purposes [19, p. 2].

Rozen's criticism of the nonmarketables must be evaluated in the context of the total cost of an anti-inflation program and not in the belief that, by eliminating the cost of the nonmarketables, we could avoid paying any cost at all.

Repercussions of Proposal. Rozen has greatly exaggerated the extent of the market impact of nonmarketables because he has misconstrued the nature of the existing market for long-term government securities. The liquidity of government securities is undoubtedly important for some investors (especially commercial banks), but Rozen has not recognized that it is much less important for other large investors. How else can we explain the enormous size which the long-term government securities market has attained *in spite of its thinness*? In part, the long-term market is thin³ because many long-term issues are not very large⁴ but the market is also thin because many buyers of long-term securities are not active traders; they buy securities to hold for income. Liquidity is not a serious problem for many large institutional holders and, therefore, the liquid nature of governments is not an important influence in many institutional investment decisions [13, p. 470]. In addition, Rozen

³ This fact has often been noted in the literature. For example [15, p. 123] [11, pp. 47-48] [22, p. 360].

⁴ In the case of many issues, ". . . buyers or sellers are unable to carry out purchases or sales exceeding one-quarter of a million dollars (or less) . . . without substantially changing the price . . ." [11, p. 48].

has overlooked the fact that a higher yield would compensate some holders for the reduced liquidity.

Proposal Misdirected. Rozen's criticism of the nonmarketables on the matter of maturities is mistaken for three reasons. First, Rozen's emphasis on the use of short-term securities to escape from a stringent monetary policy ignores the fact that, in recent years, banks have sold their intermediate-term securities to obtain funds with which to expand loans [22, p. 346]. Under the breakdown mentioned in my paper, this would not have been possible. Second, the criticism is mistaken because it is irrelevant whether banks in past periods have sometimes used their short-term securities to avoid the impact of a restrictive credit policy. Under the nonmarketables idea, the banks would not have this option because the supply of short-term securities would be limited to the amount needed for short-term liquidity purposes.⁵ That is why I stated that "except for short-term liquidity reserves, all other bank-eligible government securities be nonmarketable" [1, p. 658] and then added that "for maximum effectiveness, the supply of Treasury bills would also have to be limited" [1, p. 658, n. 2].

Third, the criticism is also mistaken because, for control purposes, the important distinction among government securities is not, as Rozen seems to think, as to maturities. The maturity classifications are relevant only to the extent that they can approximate the analytical distinctions. The important analytical distinction is between securities which the bank is free to liquidate for loan expansion and those which it is not free to liquidate for that purpose. Securities held for short-term liquidity purposes cannot be liquidated for loan expansion purposes; by and large, other securities can serve that purpose. In principle, it's as simple as that, in practice, it's not. Although bills and certificates are held for short-term liquidity reserves, not all bills and certificates are held for that purpose,⁶ and not all securities held for secondary reserves are bills and certificates.⁷ Similarly, not all investments for income are long-term securities. Under the circumstances, there is no clear-cut association, valid for all times, between the maturity of a security and its availability as a source of funds for loan expansion purposes. *No* classification of securities by maturities can correspond exactly to the analytical categories, and that is why I was careful to state [1, p. 657] that *only as a rough approximation* could we assume that bills and certificates are not troublesome and that the longer-term securities are troublesome.

II. Credit Control and Deposit Intermediaries

Reserve Requirements for Intermediaries. My analysis of reserve requirements concentrated on the differential impact of reserve requirements on the credit volumes of banks and intermediaries. Rozen has failed to refute my conclusion about the differential impact [1, p. 660 and n. 6] for two reasons.

⁵ In practice, some slack would be unavoidable.

⁶ Some bills and certificates are purchased with funds which are temporarily surplus on the customer loan market.

⁷ For example, long-term securities can serve as short-term liquidity reserves when they are within (say) 3-6 months of maturity. However, not all liquidity reserves need to be

First, he has predicated his criticisms on an erroneous inference. Rozen believes that if intermediaries held their reserves in the form of balances at the FHLB instead of as demand deposits at commercial banks, an increase in reserve requirements would bring about a "multiple impact on the total supply of intermediary credit and would make additional reserves obtainable only at the discretion of the central banking institution" (p. 189). He is not correct because the Federal Home Loan Banks' own balances are overwhelmingly held at commercial banks (except for a small amount which is held at the Treasury, and most of the Treasury's deposits are also held at commercial banks). Second, his criticism contains an analytical error. It is possible that, in mentioning the FHLB, he meant to suggest a form he believed to be "strictly comparable with the operations of the Federal Reserve System" (p. 189). However, even if the intermediaries held their reserve balances at the Federal Reserve Banks in the same manner as the commercial banks, an increase in reserve requirements could not ensure a multiple impact for the intermediaries. If both banks and intermediaries held reserves at the Federal Reserve, reserves could flow between them and, to this extent, one or the other would not have to depend exclusively on the central banking institution for additional reserves. The multiple impact could only be ensured by particular reactions of the public [1, pp. 669-70] to pressure on its liquidity when the financial institutions (both banks and intermediaries) adjust their reserve positions to the newly required levels. I stressed those reactions in my paper because they can cause the intermediaries to conform to the requirements of a restrictive credit policy even in the absence of legal reserve requirements.

Weak Impact on Both Banks and Nonbanks. Rozen correctly states that changes in credit extension would depend on idle balances, but he incorrectly concludes that my case about the differential impact of reserve requirements on banks and intermediaries depends on idle balances. Rozen's error stems from his confusing a change in credit volume with a change in credit-granting activities (which he calls credit extension). I defined a change in the amount of credit an intermediary grants as a change in the turnover of its credit [1, p. 659], but, contrary to Rozen's interpretation, my conclusion about the differential impact of reserve requirements was explicitly stated in terms of the credit *volume* of banks and intermediaries [1, p. 660]. Hence, my conclusion is independent of the presence or absence of idle balances.

Rozen argues that, since banks can escape from the restrictions of a restrictive credit policy by activating idle funds, "the weaker impact of increased reserve requirements on intermediaries will not be very relevant" (p. 190). His point would be pertinent only if reserve requirements were eliminated entirely as a credit control device. In fact, his criticism is misplaced both because commercial banks are presently required to hold legal reserves and also because many people think we ought to consider extending legal reserves to the intermediaries as well. Under those circumstances, it is both important and decidedly relevant to investigate the forms which the reserves might take

short-term, highly liquid assets. Some (which Robinson calls Class II secondary reserves) "... may be materially longer, perhaps as long as a bank can afford for other reasons" [14, p. 86].

and to determine by advance analysis whether (as is widely assumed) the reserve requirements really would have the same impact on the credit volume of both banks and intermediaries.

Reduction in Earning Capacity. It is pertinent to recall the differential impact on credit volumes when Rozen notes that "reserve requirements might affect intermediary credit extension through a reduction in earning capacity" (p. 190). Once reserve requirements have been equalized in a system with a given total of reserves, this differential impact would determine (*ceteris paribus*) how any further increase in reserve requirements would affect the earning capacity of banks and intermediaries. As shown earlier, this difference could work more against the banks than against the intermediaries.⁸

III. Reactions to Excess Demand for Money

Shifts from Demand to Intermediary Deposits. I showed that a tight money period probably would not cause significant shifts from demand deposits to intermediary accounts because, contrary to what has been feared by others [5, p. 50], a tight money period probably would not raise very much the opportunity cost of holding demand deposits for those depositors who are sensitive to movements of the intermediary deposit rates. Rozen agrees about the shift but he rejects any role for opportunity costs on the grounds that (1) intermediary deposits are held by households (who are small savers) and households do not hold large cash balances; and (2) other holders of idle balances (i.e., nonhouseholds) do not want intermediary deposits at any time (p. 190). Although we need to know a lot more about these matters, it is clear that Rozen's criticism suffers from his failure to recognize the diversity among depositors. First, although most intermediary deposit accounts are held by small savers, a significant minority of accounts are held by large savers. A recent analysis of SLA depositors in two widely separated cities showed that 16 per cent of the number of SLA accounts was in the \$5,000-and-over bracket [16, p. 24]. Moreover, although the small savers predominated by numbers of accounts, the large depositors held a very large percentage of the total volume of share accounts.⁹ Second, as I look at it, Rozen's own figures dispute his contention that households do not hold large cash balances. He has stated that 29.7 per cent of total demand deposits in insured commercial banks were held by individuals as of January 25, 1961 (p. 190, n. 10). This is equal to \$32.4 billion [9, p. 405]. He has also noted that roughly half of the amount of all personal deposits of individuals are held in accounts of less than \$5,000 (p. 190) which, of course, also means that roughly half are held in accounts of more than \$5,000.¹⁰ As of January, 1961, this meant that approximately

⁸ For a fuller discussion of the comparative competitive relations between commercial banks and SLA, cf. [2, pp. 11-21].

⁹ Of the deposits in the sampled institutions, 63 per cent were held in accounts of \$5,000-and-over; almost 28 per cent in accounts of \$10,000-and-over [16, p. 24]. I am not aware of any comparable study for MSB but in a study of the Bowery Savings Bank as of the end of 1954, 20 per cent of the number of accounts were in accounts of \$5000-and-over and those depositors held 60 per cent of the total amount due to depositors [4, p. 56].

¹⁰ Actually about 45 per cent because 5.2 per cent of deposits were unclassified [8, p. 380].

\$14.5 billion was held in large accounts. The significance of this figure can be gauged from the fact that it is about twice as large as the total net increment to share accounts at SLA and more than ten times as great as the total net increment to MSB deposits in 1961 [9, p. 12]. And this is not all. The \$5,000 level is an arbitrary division of account size and a lot of the money which would be susceptible to an opportunity-cost shift is probably held by individuals with accounts in the less than \$5,000 category.¹¹ In this connection, it is pertinent that, although Rozen attempts to minimize the possibility of a shift between money balances and intermediary deposits, the Director of Research of the U.S. Savings and Loan League has stated that “. . . a considerable proportion of gross savings inflow is represented by marginal dollars, that is, *those that waver between pure thrift and the demand deposit category.*”¹² Finally, although households hold most of the intermediary deposit accounts, the intermediary deposits held by nonprofit organizations (e.g., labor unions, pension funds, etc.) are growing in importance and should not be ignored.¹³

Deposit Shifts and Rate Differences. We do not disagree about whether the rate difference¹⁴ is one of the important considerations in determining a saver's decision in placement of deposits; obviously it is. We disagree about how to interpret the role of the rate difference in the relative decline of TD.¹⁵ To illustrate, let us posit a demand curve for time deposits as a percentage of total savings deposits (TD, SLA, and MSB). Let the X-axis measure the per cent of total savings deposits that the public wishes to hold in the form of TD and let the Y-axis measure the rate difference in the absolute terms favored by Rozen. At any moment of time, a negatively-sloped curve would show the TD share for different hypothetical rate differences. For many years, the TD share of total savings has declined but since rate differences have been constant (and have even narrowed somewhat in recent years), the change cannot be due to a rate effect; at a given rate difference any decline in the commercial banks' share must have been due to a shift of the demand curve. Rozen's statement that “time was needed to gain public recognition and acceptance of the nonbank financial intermediaries” favors my position because this growing public acceptance of the intermediaries signifies a *change in depositor prefer-*

¹¹ Only 19 per cent of the amount of individuals' personal deposits are in accounts of less than \$1,000 [8, p. 380].

¹² Don M. Dailey [18, p. 47, stress added]. It is clear from the context that “gross savings inflow” refers to the inflow of funds into the SLA.

¹³ Time deposit accounts of nonprofit organizations have also been growing in commercial banks, and the Federal Reserve has urged the banks to show these accounts separately in bank records “in view of the growing financial importance of these organizations and the presumed volatility of these deposits, particularly in response to changes in relative yields among various outlets for short-term funds” [10, p. 540].

¹⁴ In stressing his rejection of the relative interest rate differences in favor of absolute differences, Rozen has injected a false issue into the discussion. I have already shown that my conclusion holds in terms of absolute as well as relative differences [2, p. 5]. Therefore, it is indifferent for my argument which difference is selected for discussion. To accommodate Rozen's preference, let it be the absolute difference.

¹⁵ My position is based on the fact that, between 1948-1955, the commercial bank time deposits grew less rapidly than the SLA in spite of a virtually constant absolute difference between those rates [2, p. 5].

ence patterns. This change has shifted the demand curve for TD to the left and brought about a decline of the commercial banks' share in spite of a constant (and even declining) absolute rate difference.¹⁶

Availability Effect. The availability effect involves a "shift from savings (*both time and intermediary*) deposits to demand deposits . . ." [1, p. 667, italics added]. Rozen does not deny that a business holder of commercial-bank time deposits might shift from TD to demand deposits but he dismisses the possibility that individuals who hold time deposits or intermediary deposits might make a similar shift. Rozen's criticism is mistaken because he fails to recognize the different motivation which might induce deposit shifts. He seems to be thinking only of shifts which would increase the idle funds held by individuals and wonders why an economic unit would forego the liquidity and return on savings deposits by shifting from savings deposits to demand deposits. He simply ignores the possibility that, if a restrictive credit policy deprived individuals of their usual sources of credit (or made the credit too costly), households might increase their cash balances in order to spend them. Once the *possibility* of a shift has been recognized, the question for credit policy is how to increase the *probability* that the public's reaction to an excess demand for money will take the form of a direct shift from intermediary deposits to demand deposits or of an indirect shift via purchase of securities.¹⁷ Either reaction by the public would cause the intermediaries to lose reserves and, in this indirect way could oblige them to conform to the requirements of a restrictive credit policy.

IV. Credit Control and Deposit Intermediaries

Ceiling Rates and Growth Rates. Rozen's argument that not much scope remains for product competition by nonbank intermediaries fails to recognize that eliminating the rate difference can of itself serve to expand the scope for product competition. For, ignoring the problems of the transition, a reduction in the dividend rate could enhance the resources available to the SLA for increased product competition.¹⁸ Deprived of a rate difference but reenforced with a large fund, the management of the SLA industry could intensify its competition for savings deposits by using this fund to absorb part of the cost of present services or to pay for new services.¹⁹

¹⁶ This does not preclude the possibility that rate differences might bring about a further relative decline of TD at some future time and I recognized this possibility in my paper [1, p. 666].

¹⁷ Even at the present time, some depositors use their savings deposits as a source of funds to buy securities. A survey by the U.S. Savings and Loan League of the purposes for which savers withdrew \$1,000 or more from their SLA accounts during January 1961 found that 22.2 per cent of the withdrawals were for the purchase of securities [17, p. 25, errata sheet for Table 13].

¹⁸ This is less true of the MSB.

¹⁹ Space limitations preclude a further discussion of this point. The interested reader can get an idea about the kind of competition that could substitute for the loss of a rate advantage from the following issues of the official publication of the U.S. Savings and Loan League [18]; October, 1956, pp. 49-50; February, 1957, p. 34; April, 1957, pp. 41-42; June, 1957, p. 40; February, 1958, p. 54; August, 1960, p. 41.

It is misleading if not wrong for Rozen to suggest that "the competitive position of commercial banks is likely to be improved" by a uniform rate ceiling set at the highest level of rates paid by any of the savings deposit institutions. A high ceiling could doubtless benefit various *individual* banks but, for reasons I have already explained [1, pp. 665, 669] (cf. also [3, p. 145] [21]), it would not significantly affect the position of the banking system as a whole.

Impairing Intermediary Liquidity. Rozen attempts to minimize the possibility that intermediary liquidity could be impaired indirectly by a shift from intermediary deposits to demand deposits. This merely repeats the point that has already been answered in Section III. With respect to a shift towards securities, Rozen finds my objective puzzling because he apparently did not realize that I was talking about securities supplied from Federal Reserve portfolios. He states that he can see no point in trying to encourage the shift because: "Although intermediary reserves might be restricted, the volume of credit would be unchanged" (p. 193). He goes on to argue that the shift would make sense only if the intermediary deposits were used to purchase Treasury securities which would otherwise have required an expansion of the money supply to enable the banks to hold those additional securities. Rozen errs on both points. The shift can be fully effective without reference to his alternative of an expanded money supply if the securities are provided from Federal Reserve portfolios, as I intended. At the same time, if the public paid for the securities by liquidating their intermediary deposit accounts, their action would force a reduction in the volume of intermediary credit and, in addition, a reduction in the volume of bank credit.

Variability in Earnings-Price Ratios: Comment

The analysis of earnings-price ratios by Haskel Benishay [1] in a recent issue of this *Review* is of interest in so far as it provides information on the variation in the cost of capital among corporations. The concept of the cost of capital has been the subject of considerable theoretical controversy, and there is a great need for empirical research to improve the factual basis of our knowledge on the subject. It is therefore most unfortunate that the errors committed by Benishay both in formulating his model and in interpreting his findings are so numerous and serious that his results probably do more to confuse than clarify the issues.

It will be useful to begin with a brief statement of the theoretical background for the paper. According to neoclassical theory, when the future is known with certainty a firm increases its value by undertaking any investment with a rate of profit greater than the rate of interest. Those who accept the theory, let us call them capital theorists, consider problems of finance such as the determination of a corporation's optimum dividend rate nonsense problems. Under neoclassical theory, the value of a firm is independent of the way in which it is financed.

In contrast with the capital theorists, financial analysts *observe* that corporations do not use the rate of interest as the cost of capital¹ and that cor-

¹ The cost of capital is the rate of return a firm requires as a condition for undertaking an investment. It is widely accepted that the objective of the firm is the maximization

porations are very much concerned with financial policy—debt-equity ratio, dividend rate, etc. Their observations have persuaded many of them that the conclusions arrived at by means of neoclassical theory for a world of certainty are not valid when it is recognized that the future is uncertain and investors may have an aversion to risk.

The purpose of a recent paper by Modigliani and Miller [6] was to bridge the gulf between the capital theorists and the financial analysts. Their argument may be summarized as follows: Under uncertainty a corporation's cost of capital is not the rate of interest, but the corporation's earnings plus interest paid divided by the market value of its securities (equity plus debt). The cost of capital may vary among corporations in accordance with differences in their intrinsic riskiness. However, the method of finance remains of no consequence: A corporation maximizes its value by undertaking every investment with a rate of profit in excess of its cost of capital as defined above, independently of the method of finance employed. In particular, dividend and leverage policy have no influence on the value of a corporation.

Although Benishay did not explicitly address himself to the Modigliani-Miller paper, the question he tackled may be stated as follows: Does the explanation of the considerable variation in earnings yield (earnings-price ratio) among corporations support the Modigliani-Miller theory?² Benishay classified his independent variables as "corrective" and "risk" variables. Risk variables were included because a corporation's earnings yield may be expected to vary with leverage, earnings instability, and other risk attributes of a share. The corrective variables have the following rationale: If a share has a price of \$50 and current earnings of \$10, the *measured* yield on the share is .20. The *true* yield on the share is also .20 if the expected earnings in each future period are also \$10.³ However, if the expected earnings are only \$5 per period, the true yield is only .10, although the measured yield is .20. The dependent variable can only be a measured yield, and the purpose of the cor-

of its value (i.e., the value of the existing ownership equity). In this event the cost of capital is a rate of return such that any investment with a higher rate raises the value of the firm and vice versa. It is evident that under neoclassical theory a firm takes the rate of interest as its cost of capital.

² There is no difficulty in the fact that the Modigliani-Miller ratio includes interest in the numerator and debt in the denominator, what might be called the gross or leverage free earnings yield. Under their theory a simple linear relation holds between their ratio and the earnings-price ratio. Let y = earnings-price ratio, q = ratio of earnings plus interest to equity plus debt, h = leverage ratio, and i = rate of interest. Under the celebrated Modigliani-Miller theorem q is independent of h , and

$$y = q + h(q - i)$$

Hence, y varies with h and it varies in the same manner as q with every other variable. It is also true that, under their theory, a corporation's cost of capital is equal to q . That is, a corporation increases the market value of the existing ownership equity by undertaking every investment with a rate of return greater than its value for q , regardless of the method of finance employed.

³ By true yield I mean the rate of discount that equates the future earnings stockholders expect with the price of a share. Benishay refers to this quantity as "the theoretical concept of a rate of return on equity capital" [1, p. 81].

rective variables is to account for the variation in measured yield that does not represent variation in true yield (the significant economic variable) among shares. The introduction of corrective variables is the main contribution of the paper, and they will be our primary concern.

Since a corporation's earnings are subject to wide year-to-year fluctuations, the earnings in any one year may not represent what investors believe the corporation is able to earn. For this reason Benishay uses as his dependent variable, y , a weighted average of the corporation's earnings for the nine years up to and including the cross-section year⁴ divided by the market value of the equity outstanding in the cross-section year. His first corrective variable X_1 is the rate of growth in earnings over the nine-year period up to and including the cross-section year. It is included because the averaging process for obtaining y biases its value downward for a corporation with a trend rate of growth in earnings. The second corrective variable, X_2 is the rate of growth in the market value of the common equity over the nine years. If expected earnings have been recently re-evaluated, the measured yield will be in error as an estimate of the true yield. X_2 is introduced on the grounds that the re-evaluation of expected earnings will be correlated with the rate of growth in the value of the stock. Hence, X_2 is a means of discovering error in the measured yield. Benishay found no correlation between y and X_1 . There was statistically significant correlation with X_2 , but his rationale for this finding is open to question.

The third corrective variable, X_3 , is the log of the average dividend pay-out rate for the three years up to and including the cross-section year. There was statistically significant inverse correlation between y and X_3 , and I judge that X_3 contributed most to explaining the variation in y among the corporations. Inverse correlation between earnings yield and dividend pay-out rate is usually interpreted as evidence against the Modigliani-Miller theory. Their position is that a rise in the dividend with earnings given should leave share price unchanged.⁵ The opposite view that the dividend rate has an influence on price and earnings yield has wide acceptance in financial circles on pragmatic grounds, and has been investigated theoretically in my writings [4] [5].

Benishay acknowledges the existence of this position with the statement, "A notion seems to prevail in the financial literature, that because investors prefer distribution to retention of earnings, the pay-out ratio and the rate of return are negatively correlated" [1, p. 83]. However, he finds no substance in this notion. He attributes the correlation between earnings yield and pay-out rate to "... the effect of errors in the measurement of earnings. If measured earnings are an overestimate and dividends are a stable proportion of

⁴ Using a large sample of corporations Benishay ran cross-section regressions of y on the corrective and risk variables for the years 1954-57.

⁵ More exactly, they maintain that price should rise (fall) if the rate of return on the investment financed by a reduction in the dividend is above (below) q . However, this would not cause inverse correlation between payout rate and earnings yield. If anything, the comparatively favorable tax treatment accorded capital gains and the likelihood that corporations with high rates of return on investment have lower pay-out rates would lead one to expect positive correlation between pay-out rate and earnings yield.

expected income; the rate of return is 'too high' and the pay-out ratio 'too low.' This will introduce into the relationship a negative spurious correlation" [1, pp. 83-84]. The Modigliani-Miller [7, pp. 666-68] statement of what I (and also Benishay) believe is the same position is that corporations pay a stable fraction of *expected* income in dividends. Actual income fluctuates considerably and is a poor estimate of expected income, so that correlation of stock price with dividends is due to the "informational content of dividends" with respect to expected income.

This interpretation by Benishay of the correlation he found between earnings yield and pay-out rate is, to put it mildly, not convincing. He took great pains to deal with the problem of earnings measurement without reference to the dividend rate. Recall, y is based not on current earnings but on a weighted average of earnings, and two corrective variables other than the pay-out rate are used to further correct for the difference between actual and expected earnings. Yet Benishay still found it necessary to introduce the pay-out rate.⁶

Returning to the other corrective variables, X_1 and X_2 , closer examination reveals that even within the framework of his theoretical preconceptions Benishay's model is a seriously defective instrument for realizing his objective—explaining the variation in yield among common stocks. Assume a sample of corporations with the following attributes: (1) All corporations have no debt and have the same leverage-free riskiness. This eliminates the need for the risk variables. (2) The Modigliani-Miller theorem that the earnings yield is independent of the pay-out rate holds true. This eliminates the need for X_3 . (3) Finally, the amount each corporation is expected to earn on its existing capital can be observed free of error. This eliminates the need for X_1 and X_2 . Under these assumptions y^* , the true yield, is the same for all corporations in the sample. According to Benishay, the measured yield, y , should also be the same for all corporations. In fact, with y^* the same, y would vary among the corporations in the sample. As Bodenhorn [2] has shown and Modigliani and Miller [7, pp. 662-63] recognized independently, all corporations will have the same y only if each has a rate of return on new investment, r , that is equal to y^* .⁷

⁶ When Modigliani and Miller advanced the informational content explanation of correlation with the pay-out rate, what they seemed to have in mind were situations where current income alone was used in the model. One wonders at the implications of the argument when it is used without proper caution. For instance, one might imagine a financial analyst would respond as follows when called upon to advise a corporation that is considering a reduction in the dividend to finance investment: "You need have no fear a reduction in the dividend will depress the price of your stock. What you must keep in mind, however, is that investors believe you pay a stable fraction of expected income in dividends. Therefore, the informational content of the dividend reduction will lead investors to believe your expected income will decline. Of course the price of your stock will fall but this will be due not to the dividend reduction but to its informational content."

⁷ A corporation will have $y = y^*$ if $r = y^*$, because it has no leverage. The more general condition is that $r = q^*$, where q^* is a firm's true cost of capital. (Since measured and true earnings yield may differ, q and q^* may differ.) With zero leverage $y^* = q^*$. With leverage varying y^* will vary among the corporations in the sample, but q^* will not. The value of y^* for each is $y^* = q^* + h(q^* - i)$. If $r = q^*$, for all corporations, they all will have the same $q = q^*$, and for each y will be equal to the value of y^* given

With $r = y^*$ the earnings generated by investment will just cover the cost of the funds provided and leave the expected earnings on the existing capital unchanged. By contrast with $r > y^*$ a return of r will be earned on investment and a return of y^* will be paid for the funds provided. The excess will accrue to the existing stockholders, and investors will expect the earnings on the existing equity to increase over time. The price at which the stock will sell in relation to current earnings will thereby be raised. In other words, with y^* the true yield, the observed yield will be $y < y^*$. Therefore, a corrective variable Benishay should have used is $q(r - y^*)$ where q is the investment rate.

It may appear that the two corrective variables X_1 and X_2 have some similarity with the variable just proposed. However, they differ in important respects from $q(r - y^*)$. As to X_1 , I have shown elsewhere [4] that the rate at which a corporation's income grows is roughly equal to the product of its rate of profit on investment and b , its retention rate. Hence $rb \sim X_1$. Assume a corporation with $r = y^*$ has been retaining and investing a large fraction of its income. X_1 will be large, but for this corporation no correction should be made in y as a measure of y^* . By contrast another corporation with $r > y^*$ may have a low b and use other sources of funds to finance investment. For this corporation y will seriously underestimate y^* , and a large correction is needed. However, X_1 will be lower than the value for the previous corporation.⁸ It is evident that X_2 is no better than X_1 as a corrector for error in the measured yield due to differences between a corporation's cost of capital and the profitability of its investment opportunities.

The reason that Benishay offered for the statistically significant correlation between y and X_2 is most unimpressive. Inverse correlation between y (earnings divided by price) and rate of growth in price is almost inevitable, and it could arise for a number of reasons, among which a recent re-evaluation of expected income is only one. For instance, assume that confidence in expected earnings has recently changed in varying amounts for the corporations in the sample. For corporations in which there was a rise in confidence the share price would rise and *both* measured and true yield would decline. The result would be inverse correlation between y and X_2 , but under this cause for the correlation there would be no error in y as an estimate of y^* for a corporation. In contrast, Benishay would have someone interested in the value of y^* for a corporation use X_2 to correct the measured yield.

Benishay's model contained four risk variables, and all but the last can be dealt with quite briefly. X_4 , income stability, is the mean of earnings for the nine years divided by the standard deviation of earnings around its trend. There was no correlation between y and X_4 . Aversion to risk and the use

by its leverage rate. Note that we are here accepting the assumptions of the Modigliani-Miller theory under which q^* is a corporation's cost of capital. Also, by assuming no leverage we may continue to refer to y^* as the cost of capital.

⁸ The absence of correlation between y and X_1 that Benishay found may possibly be explained as follows: There is positive correlation between y and b , and there probably also is an inverse correlation between y and r . The result will be no correlation between y and rb , and $rb \sim X_1$.

of variability in past earnings to measure risk are widely accepted. It would therefore seem likely that the lack of correlation reflects on Benishay's model and/or his measurement rules. X_5 , equity stability, is analogous to X_4 with equity value substituted for earnings. We would expect y and X_5 to be negatively correlated, but the data produced positive correlation. Benishay interpreted this result as evidence that investors have a preference for price fluctuations due to their speculative urge.⁹ X_6 , a corporate-size variable, showed significant inverse correlation with y . This finding is the only significant correlation for which he could provide a plausible explanation.

Benishay's last variable was the debt-equity ratio. X_7 proved to be inversely correlated with y , and in explaining this result Benishay provided another strange piece of reasoning. He stated that the "debt-equity ratio can be interpreted in two ways: (1) if it represents deviations from its equilibrium value, then it ought to be positively associated with the rate of return. (2) If it were to be measured at its equilibrium level it ought to be negatively correlated with the rate of return, since then it becomes a measure of safety" [1, p. 92]. What does Benishay mean by equilibrium value? If his dependent variable had been ρ , earnings before interest divided by equity plus debt, then under Durand's [3] theory one could talk about an equilibrium leverage ratio, the one that maximizes share price. Under the Modigliani-Miller theory there is no such thing as an equilibrium value. However, Benishay's dependent variable was y and not ρ and everyone including the writers just mentioned agree that a corporation's earnings yield increases with its leverage. His finding of inverse correlation between y and leverage is contrary to generally accepted theory.

Benishay's "measure of safety" explanation for the correlation may be stated more clearly as follows. The other risk variables did a poor job of accounting for the variation in the leverage-free risk among corporations, and the corrective variables did a poor job of accounting for $q(r - y^*)$. Since secure profitable corporations are likely to borrow more than unstable unprofitable ones, the correlation between y and X_7 is due to the variation among corporations in stability and profitability and not the variation in leverage, other things the same. In short the results further demonstrate that the measurement of the other variables was unsatisfactory, and one cannot infer that an increase in leverage reduces the earnings yield at which a share will sell.

Smoothing past earnings and using corrective variables are promising lines of attack in the analysis of variation in earnings yield among shares. However, Benishay's choice of variables and his explanation of the findings were most unfortunate.

MYRON J. GORDON*

* A more reasonable explanation is that the period used to obtain X_5 for each corporation was one in which the trend in share prices was upward. The shares that rose the most are those that would have small values for y . The shares that changed in price the most (rose in this period) probably also had the greatest fluctuations around their trend values in relation to their mean price over the period, i.e., the highest values for X_5 .

Variability in Earnings-Price Ratios: Reply

Gordon's primary criticism is directed at my interpretation of the regression performance of the pay-out ratio variable. In my work I have ascribed the negative relation between the pay-out ratio and the measured rate of return on equity (earnings-price ratio) to errors in the measurement of earnings. In several articles [3] [4] [5] [6], all variations on the same theme, Gordon has ascribed this relation to market preference for dividends.¹ Apparently he believes that my explanation has no merit either in the context of my research or in the context of his own work, and that his explanation remains unimpaired. Gordon's secondary criticism is aimed at the choice of other independent variables included in my model in the apparent belief that their alleged defectiveness lends additional support to his main criticism. In so doing he fails to realize that if he were correct in his view that the other variables were erroneously included, the negative empirical relation between the pay-out ratio and the earnings-price ratio would become even more doubtful, lending less rather than more support to his main argument.

In this note I shall first attempt to demonstrate the merit of the errors-of-measurement explanation. I shall then deal with his criticism of my use of variables other than the pay-out ratio.

I. The Errors-in-Measurement Explanation

I believe that even a weighted average of past book earnings will diverge from expected income and that consequently the pay-out ratio coefficients will be negatively biased. The divergence between a mean of past book earnings

¹ He presents another rather mechanical explanation which we shall not examine.

and expected income will consist of three components constituting together a sizable proportion of expected income: (1) the difference between the mean of book earnings derived from the time-series sample and its expected value; (2) the misrepresentation of actual earnings by book earnings; (3) the difference between actual earnings and expected income. In order to assess the resulting bias in the pay-out ratio coefficients we shall trace the error effects in a simple linear regression of the log of the earnings-price ratio on the log of the payout ratio.² We shall establish the existence of the downward bias of the pay-out ratio coefficients and try to ascertain its order of magnitude.

Let the error in the measurement of earnings be $1 - V$, so that measured earnings equals expected income times V ; measured earnings has no error when V equals 1. Our regression can be written: $\log [(\text{expected income}) V / \text{equity}]$ on $\log [\text{dividends} / (\text{expected income}) V]$ or $[\log (\text{expected income}) + \log V - \log (\text{equity})]$ on $[\log (\text{dividends}) - \log (\text{expected income}) - \log V]$.

Let: the log of the true rate of return be y . Hence $\log (\text{expected income}) - \log (\text{equity}) = y$. Let $\log V$ be z ; log of measured rate be $(y + z)$. Let log of true pay-out ratio be x ; so that $\log (\text{dividends}) - \log (\text{expected income}) = x$. Let log of measured pay-out ratio be $(x - z)$. And let z be independent of y and x . Then:

$$B_{(y+z)(x-z)} = M_{(y+z)(x-z)} / M_{(x-z)(x-z)}$$

where $B_{(y+z)(x-z)}$ is the population regression coefficient of the measured rate of return on the measured pay-out ratio expressed as a ratio of the appropriate moments; and

$$B_{yx} = M_{yx} / M_{xx}$$

is the corresponding population regression coefficient of the true rate of return on true pay-out ratio.

We would like to trace the effect of the measurement error upon $B_{(y+z)(x-z)}$, when $B_{yx} = 0$, when there is no correlation except due to error.

$$(1a) \quad M_{(y+z)(x-z)} = M_{yx} + M_{z(y-x)} - M_{zx}$$

but since $M_{z(y-x)} = 0$

$$(1b) \quad M_{(y+z)(x-z)} = M_{yx} - M_{zx}$$

Consequently

$$(1c) \quad M_{yx} = M_{(y+z)(x-z)} + M_{zx}$$

also

$$(2a) \quad M_{(x-z)(x-z)} = M_{xx} - 2M_{zx} + M_{zz};$$

but since $M_{zx} = 0$

$$(2b) \quad M_{(x-z)(x-z)} = M_{xx} + M_{zz}$$

and consequently

$$(2c) \quad M_{xx} = M_{(x-z)(x-z)} - M_{zz}$$

² We shall assume that all relevant variables except for the error are constant.

Therefore

$$(3) \quad B_{yx} = M_{(y+z)(x-z)} + M_{zz}/M_{(x-z)(x-z)} - M_{zz}$$

If $B_{yx}=0$ (as I believe), then $M_{(y+z)(x-z)} = -M_{zz}$, and therefore we would expect:

$$(4) \quad B_{(y+z)(x-z)} = -M_{zz}/M_{(x-z)(x-z)}.$$

Stated verbally we would expect a negative coefficient, even when B_{yx} , the true regression coefficient, equals zero.

Having established the existence of the downward bias of the pay-out ratio coefficient I shall try to ascertain its order of magnitude. My work provides an estimate of $M_{(x-z)(x-z)}$, the denominator of expression (4), equal to .015. If we assume that the error $1 - V$ equals $-.25$ and $+.21$, then z will be plus or minus .1; M_{zz} in expression (4) will equal .01 and consequently the measured regression coefficient $B_{(y+z)(x-z)}$ would equal $(-.010/.015) = -.66$. In a similar fashion, if the error $(1 - V)$ averages about ± 13 per cent the measured regression coefficient would inevitably be about $-.30$.³ Therefore, if errors of the magnitudes considered are acknowledged to be associated with the measurement of expected income, negative correlations between the pay-out ratio and the earnings yield will be spurious.

II. Other Criticism

1. Gordon provides what he believes is a proof of the "defectiveness" of my model. He criticizes my use of X_1 and X_2 to correct measured income and mistakenly contends that he has an alternative and a better way to correct for the error. He presents a model based on the assumptions that: (1) corporations have no debt; (2) the earnings yield is independent of the pay-out ratio; (3) earnings expected on existing equity is measured without error, and known with certainty. He proceeds to obviate his third assumption by implicitly assuming that corporations' expected rate of return on new investment, r , is unknown which renders earnings expected on existing equity only partially known. He concludes that income expected on existing equity is an increasing function of r . He further concludes that the error of measuring expected income is $q(r - y^*)$ where q is the investment rate and y^* is the true rate of return on existing equity. He does not specify how, y^* , which was implicitly assumed known, as well as r and q are to be determined empirically. He does not realize that in my work I have tackled precisely this empirical problem by using X_1 and X_2 .⁴ He does not apprehend that by acknowledging the existence of errors of measurement of earnings he actually acknowledges

³ Assessing the order of magnitude of the bias on the basis of assumptions about the order of magnitude of the error was suggested to me in the context of another empirical investigation by Lawrence Fisher.

⁴ Recall that y^* = expected income on existing equity/market value; r = expected income on new investment/cost of new investment; q = investment rate. In order to know y^* one must measure expected income on existing equity without error. Gordon has not suggested how. In order to correct y^* it is necessary to measure r without error. Again Gordon has not suggested how. Therefore, presenting $q(r - y^*)$ as a corrector for y^* where both r and y^* are unknown constitutes no solution to the problem of correcting y^* .

a spurious negative correlation between the pay-out ratio and the earnings yield even when the earnings yield is independent of the pay-out ratio. Furthermore, he does not grasp that if X_1 and X_2 were in fact doing a poor job of correction, the expected spurious correlation between the pay-out ratio and the earnings yield would be even higher.

Gordon criticizes in more detail my growth in earnings variable, X_1 . He considers two companies one with the rate of return on new investment, r , equal to the rate of return on existing equity, y^* , the other with $r > y^*$. He artificially assumes that the retention rate, b , is sufficiently lower for the second company to render its rb smaller than rb of the first, and wrongly concludes that in the case of the second company, X_1 will not correct properly. He forgets however that X_1 measures growth from *any* source, not necessarily from retained earnings. If r for the second firm is high the level of new investment will be high. Retained earnings and/or external funds will be used by the firm to take advantage of the opportunity afforded by a high r and their *combined* influence will be measured in X_1 .

But another and more important point must be made in this connection. It is *expected* growth which we aim to measure in X_1 and *past* growth which we actually measure. And only if past and expected growth in earnings are correlated to an appreciable degree, will X_1 accomplish its task as a corrector. My results suggest that the two are correlated but not to an appreciable extent.

2. Gordon argues that my explanation (shifts in expected income) of the negative correlation between the earnings-price ratio and growth in equity is not the only possible one: He maintains that possible changes in the earnings yields of companies in my cross-section can serve instead as an explanation. I considered this alternative before excluding X_2 in my model and discounted it because I felt that its actual contribution was negligible: changes in prices of shares of stock are generally caused by shifts in expected income not by changes in earnings yields, or put differently, true earnings yields are far more stable through time than expected income.

3. Gordon maintains that since "aversion to risk and the use of variability in past earnings are widely accepted" (pp. 207-8) stability in earnings, X_4 , and the earnings yield should have been, but in fact are not, correlated in my work. Recall that the partial regression coefficient of X_4 in my work is consistently negative in all four cross-sections (t ratios: 1.50; 1.55; 1.74; 1.01), and that this supports rather than contradicts the hypothesis of preference for earnings stability; also the fact that the error element in measured earnings, from which X_4 is computed is great, renders X_4 inaccurate and reduces its coefficients.

4. Gordon expects equity stability, X_5 , to be negatively correlated with the earnings yield for the same reasons that he would expect a negative correlation between earnings' stability, X_4 , and the earnings yield. But the two concepts of stability are distinctly different although common elements make them positively correlated. Consequently, there may be an aversion to equity stability even though earnings stability is preferred.

A considerable amount of the total outstanding equity is held and traded by

individuals who are in higher income brackets and/or have a high ratio of nonhuman to human capital. These individuals will tend to be less fearful of equity volatility, because of their easier access to cheaper borrowing in emergencies, and could be more inclined toward speculation; consequently they may prefer volatile equities. If the supply of variable-price stocks is limited in relation to the number of individuals in the market who are willing to buy them at prices which are *ceteris paribus* higher than those of stable-price stocks, then equilibrium prices of variable-price stocks will be higher than those of stable-price stocks. As a consequence of the preceding considerations, I see no a priori reason to believe that ascribing the positive correlation between equity stability and earnings yield to a net market aversion to stable equities is ill-founded. I believe that my interpretation is reasonable.

5. Gordon claims that my findings of inverse correlation between the earnings yield and the debt-equity ratio is contrary to generally accepted theory and attributes to me the inference that an increase in a firm's leverage reduces the firm's earnings yield. Gordon's conclusions are erroneous for two reasons:

a. He ignores the fact that firms in my study belong to several industries having varying risks and that no measure of industry risk (coefficient of variation of equity earnings plus interest) is included in my regressions. Consequently, he fails to note that in the context of my study debt-equity is in fact a measure of safety, not of risk, and should not be expected to be positively associated with earnings yield. He also fails to recognize that my interpretation is not at variance with the theory that in an individual firm the earnings yield increases with leverage.

b. Gordon ignores the complementary explanation provided by my article, that in the context of my study the debt-equity ratio is a measure of size and, as such, a measure of safety.

6. The following statement in my article explains why the debt-equity ratio is a measure of size: "In the multiple regression, X_6 , equity value, is entered along with the debt-equity ratio as an independent variable. Therefore, the regression relationship of the debt-equity ratio with the measured rate of return is determined while holding equity value constant, which in turn may make the debt-equity ratio in the context of this study a measure of size and thus account for the negative relationship with the dependent variable" [1, p. 92]. If another variable, debt plus equity, were included in the regression along with the debt-equity ratio the coefficients of the latter might have changed signs.

7. Gordon questions my use of the concept of equilibrium debt-equity ratio to explain the inverse correlation between debt-equity ratio and earnings yield. My assumptions and their implications are presented below.

a. In my framework, as in Durand's [2, p. 644], the debt-equity ratio of a firm in a given "risk equivalent class" [7, p. 265] is not independent of the risk attributed to that class. Specifically:⁵ firms belonging to a higher risk class, a class whose coefficient of variation of earnings plus interest is higher, will

⁵ It is independent in Modigliani and Miller's [7, p. 278] framework.

FIGURE 1

tend to have lower optimum debt-equity ratios at which share prices are maximized.⁶

b. We agree that within a risk-equivalent class the earnings yield is equal to the average cost of capital when the debt-equity ratio equals zero, and that it increases uniformly as the debt-equity ratio rises.

c. It is also commonly agreed that in a cross-section of firms from several risk-equivalent classes (industries) the cost of capital and the earnings yield are positively associated and that each is in turn positively associated with

⁶I believe that Modigliani and Miller's conclusion, that there is no optimum leverage, results from the fact that they dismiss two important factors [7, p. 274]: (1) the possibility that corporations are able to borrow at rates lower than individuals; (2) the effect of the probability of bankruptcy loss and the fact that this probability rises faster with an increase in debt-equity of firms with a higher coefficient of variation of earnings plus interest.

In their disclaimer of the optimum leverage view [7, p. 283] Modigliani and Miller present scatter diagrams of oils and utilities relating the average cost of capital (earnings plus interest divided by market value of equity and debt) to the debt/debt-plus-equity ratio. The optimum-leverage claim is borne out by interindustry comparison of the very data which appear to lend it no support on the basis of intraindustry comparison. Although no relationship is discernible in each scatter diagram, a negative and a significant relationship emerges when the two scatter diagrams are pooled; the higher is the cost of capital the lower is the debt/debt-plus-equity ratio. The ratio of debt to debt-plus-equity is consistently lower for the oils whose earnings plus interest are more variable, higher for the utilities whose earnings plus interest are less variable; its median for oils is about half of its median for utilities; its ranges for the two industries hardly overlap. Clearly firms belonging to a higher risk class tend to have lower debt-equity ratios.

the coefficient of variation of earnings plus interest for the class, i.e., with risk for the class.⁷

If the three preceding propositions are accepted, two conclusions follow: (1) The debt-equity ratio is negatively associated with the earnings yield in a cross-section of firms from several industries as shown in Figure 1. Dotted lines represent the earnings-yield schedules, solid lines the average cost of capital schedules for the various risk classes. The *o*'s represent optima. The *x*'s are actual observations of firms' debt-equity ratios and their respective earnings yields.

(2) In a cross section of firms from several industries the deviation of a firm's debt-equity ratio from the optimum debt-equity ratio of the firm's class (*d* in Figure 2), will be positively associated with the difference between a firm's actual earnings yield and the earnings yield for an unlevered firm in the firm's risk class (*y* Figure 2).

FIGURE 2

Conclusion (1) will apply to empirical results in a regression of the earnings yield on the debt-equity ratio where the coefficient of variation of earnings plus interest is not included and is thereby not held constant. Conclusion (2) will apply to empirical results in a regression of earnings yield on debt-equity where the coefficient of variation of earnings plus interest is included and is thereby held constant.

The firms in my cross-section are from several industries and the coefficient of variation of earnings plus interest is *not* included in the regression; therefore Conclusion (1) applies: a negative association between earnings yield and the debt-equity ratio is to be expected since the debt-equity ratio has

⁷ Risk is usually defined in terms of the coefficient of variation of earning plus interest.

come to represent safety and the earnings yield includes a premium for the risk of the class.

It is hoped that this discussion in conjunction with Gordon's comment will foster an awareness of the difficulties involved in utilizing to advantage a multiple regression analysis of variables measured with error.

BOOK REVIEWS

General Economics; Methodology

Ocherki po sovremennoy sovyetskoy i zarubezhnoy ekonomike, Sbornik statey, Vypusk 1 (Essays on Contemporary Soviet and Foreign Economics—A Collection of Articles, 1st issue). Edited by N. M. OZNOBINA. MOSCOW: Gosplan Publishing House, 1960. Pp. 307. 97 Kopecks.

This miscellany is the work of the young economists on the staff of the Scientific Economic Research Institute of the State Economic Council of the USSR. Most of the chapters are devoted to planning problems which were raised at the 21st meeting of the USSR Communist Party and the July 1960 Plenary Session of the Party Central Committee.

The collection is highly readable, and the application of statistics and mathematics to economics is reminiscent of *Econometrica* in its salad days of the 1930's before the lemma specialists took over. Some articles are stimulating while others belabor the obvious, and all but the last two are well worth reading. The small press run (only 5,500 copies) is surprising.

The lead article by A. I. Anchishkin and B. P. Plishevsky describes a method of recomputing national income and product in prices that approximate costs. The authors feel that certain costs are not reflected in prices because of what I translate as "peculiarities in the present system of price determination." They also show a healthy concern for the relationships between income, consumption, and savings, between sectors, and between industries. They conclude *inter alia* that more study of the pricing system is needed to see what can be done to improve it.

V. P. Zhivin and A. I. Klinsky write on coefficients of "total expenditure" (i.e., direct inputs of raw materials plus indirect raw material inputs in the form of finished products) and the interindustry input-output balance. Unlike the coefficient of direct input of raw materials (norm), the coefficient of total input varies with changes in structure of the industries in question and with the changing nature of interindustry relationships. The use of input-output matrices is presented as a way to get more realistic input coefficients (with electronic computers) and to use less planning manpower.

F. N. Klotstvov's input-output analysis is applied to the problem of working out a planned interindustry balance. He is looking for a better expression of the relationship between production, consumption, and investment because the existing system of norms is not sufficiently responsive.

The remaining articles on the Soviet economy are of a somewhat narrower scope. K. G. Said-Galtsev considers a new classification of "basic funds" (i.e., capital) which takes recent economic changes and technological progress into account and makes possible the computation of more realistic depreciation schedules. T. K. Popova proposes a variety of significant ratios to analyze the regional distribution of the labor force. A. E. Zholkevich discusses pro-

duction indicators for the iron and steel industry, and E. B. Lukyanov appraises the economic efficiency of its development in Siberia and Kazakhstan.

Yu. M. Kogan studies the potentialities of natural gas as a fuel for thermal electric power stations, with detailed data on the costs of pipelines and of competing fuels. A. T. Zasukhin analyzes prospects for development and specialization in the machine-tool industry. E. A. Ivanov examines the length of time required to complete different kinds of construction work and the effect on planning for new construction of hangovers of uncompleted work from earlier periods.

V. F. Mashenkov writes on planning and computing labor productivity on kolkhozes, and M. Ya. Lemeshev on the problem of specialization of kolkhozes in the present economic situation. The latter provides some data for individual farms on the percentage distribution by product of labor inputs, costs, and receipts from sales.

The above papers all represent solid journeymen work in applied economics, though much that seems familiar to the Western reader is written with a certain pioneering fervor. The last two articles are not up to the same standard, possibly because of the lack of complete documentation on Western countries in the USSR.

V. M. Kudrov covers some well-worn ground on international comparisons of national income. The upshot is that per capita military expenditures in the NATO countries are horrendous, and that UN statistics artificially lower other countries' national income relative to that of the United States. N. V. Barabanov recomputes French national income and concludes that, so far as the workers are concerned, "the post-war boom did not profit them as much as was headlined in the bourgeois press."

A Personal Interview Survey of College Economics Teachers. By ANN F. BRUNSWICK and PAUL B. SHEATSLEY. Chicago: National Opinion Research Center, 1961. Pp. 55.

This is a report based on one- to two-hour interviews with a sample of nearly 400 college economics teachers at 113 colleges. The interviews were conducted by the National Opinion Research Center of the University of Chicago on behalf of the American Iron and Steel Institute. The study was designed to reveal the personal characteristics and background of college teachers of economics and their attitudes toward assumptions and emphases in the undergraduate economics curriculum. The report is supplemented by a separate appendix containing the detailed statistics.

Some of the interesting results are these: four-fifths of the economists in the sample are under 50 years of age and a third are under 35; the average amount of teaching experience is 10 years; the average annual income from all sources is \$9,000 but only 30 per cent are entirely dependent upon their teaching salaries; two-thirds were sons (or daughters) of business and professional families; nearly a fifth were born abroad and more than a third of their fathers were born abroad; a quarter profess to no religion; one-tenth

report Republican political affiliation, half regard themselves as Democrats, and the remainder are "independent"; 80 per cent voted for Kennedy and 75 per cent for Stevenson; almost all read the *American Economic Review*; the other journals most frequently read in the order mentioned are *Journal of Political Economy*, *Quarterly Journal of Economics*, *Review of Economics and Statistics*, and *Economic Journal*; most had criticisms of the undergraduate economics curriculum or the principles course, but there was little agreement as to what might be done about them (no one suggestion was offered by more than 10 per cent of the sample); there was general satisfaction with the balance between theory and applied problems but 60 per cent say they stress theory while 25 per cent say they stress applications; most report that they try to teach without ideological or political bias and most are satisfied with the relative emphasis given to the viewpoints of labor and of industry; the overwhelming majority (86 per cent) believe that "basic values should be brought out in teaching economics," but they disagree sharply on what these values should be; in general, the economics teachers do not make extensive use of visual aids and other "modern" teaching devices.

The random list of factual results above will perhaps indicate the nature and scope of the study. Those interested in the present condition of the economics profession will find this a rewarding source.

HOWARD R. BOWEN

Grinnell College

Graphical Economics. By J. K. EASTHAM. Chicago: Quadrangle Books, Inc., 1961 (original edition 1960). Pp. x, 333. \$6.00.

The author, who is senior lecturer in economics at Queens College, University of St. Andrews, Dundee, has produced an intermediate level textbook which presents the bulk of the standard propositions in microeconomics, money, taxation, trade and macroeconomics. The title correctly states the analytical emphasis of the book. Standard, two-dimensional analytical graphs are used profusely in conjunction with clear direct prose to illuminate the subject matter. Upon occasion, algebraic proofs are introduced, some of which are more than necessarily complex, yet the reader needs very little mathematical background to follow them. In the chapter on Income and Employment, interesting use is made of a circuit flow diagram based upon electrical circuitry. The analyses presented are, as the author states in his preface, not novel. Where Eastham can attribute authorship to the constructions used, he does so, but this occurs relatively infrequently.

This is definitely a book in theory as the term is generally understood. Eastham states that the central task of economics is "to formalize the process of decision-making," and he gives virtually no attention to empirical data, the testing of hypotheses, nor the use of theory for prediction. The book likewise avoids involvement with particular institutional arrangements. For that reason, it is suitable for U.S. classes despite its British setting. Even the chapter on money requires minimal supplementation.

The author states that after the manuscript was drafted, parts of it were rewritten to make it more useful to executives. The reviewer is rather skepti-

cal about the direct usefulness of this form of analysis to businessmen. The book would have been strengthened both as a textbook and as a handbook if the basic principles of managerial accounting, as presented by Earley, and linear programming as presented by, say, Dorfman, Samuelson and Solow, had been included. The basic rationale of these modern developments has been presented by these authors in graphic form, and the application of a marginal-style analysis to the multi-input, multiproduct firm is bound to make a stronger impression on businessmen than will traditional two-dimensional marginal analysis. Students can benefit equally.

It is unfortunate that welfare economics as a separate subject is left out, particularly so because part of the chapter on taxation considers the excess burden of indirect taxation as presented by Joseph, but not the more recent criticisms by Little and Friedman. Eastham is careful to confine his presentation to the individual taxpayer, but explicit treatment of the implications of interpersonal comparisons of utility (which pass unmentioned) would be advantageous, and would involve no departure from the general tenor of the text. For example, Eastham speaks of the "... general rejection of utility theory ..." as having destroyed "... whatever plausibility the arguments [for progressive taxation] ever had ...", but accepts the appropriateness of indifference curves as a measure of the burden of taxation three pages later.

In general, the book is well done technically and the constructions and theorems are correctly drawn and proved although the book contains a score of minor slips, graphs misnumbered in the text, and mislabeled or unlabeled intersections that a good proofreader would have caught. Four examples may help prospective users decide whether or not the slips seriously impair the book for their purposes. Eastham overoptimistically states (p. 50) that empirical and theoretical demand curves may be identical. His demonstration of the need for different elasticities for profitable price discrimination is either faulty or the manner of use of subscripts seriously misleading although his conclusion is correct (p. 125). When first-degree discrimination in the product market is considered (p. 131), he fails to note that the demand curve becomes the marginal revenue curve and thus falsifies his analysis. Twice (pp. 124, 200) the most profitable output for a firm is described in the textual material as determined where the maximum distance between the average cost and the demand curve exists although the falsity of this statement is illustrated by the figures to which reference is made. Some would quarrel with a number of details of analysis and some definitions, notably his treatment of oligopoly, which is ostensibly associated with product differentiation and/or selling costs and is confined to those cases where a no-profit equilibrium is attained. Curiously, the demand curve with the Sweezy kink is not discussed.

In his effort to construct a book that will make the more significant propositions in economics accessible to the intermediate-level college student and to the more philosophically inclined businessman who lack training in advanced algebra and calculus, Eastham has done well using many graphs and relatively few words. For those who like the graphical approach, this is a useful book.

DEAN A. WORCESTER, JR.

University of Washington

Introductory Economics. By NORMAN F. KEISER. New York: John Wiley & Sons, 1961. Pp. xiii, 545. \$6.50.

This introduction to economics is a competently written textbook for use in one-semester courses. It is designed to stimulate student interest in today's major problems and issues of political economy, and at the same time to advance economic understanding in terms of an apparatus and technique of thinking about these problems and issues. Emphasizing both institutional description and elementary economic analysis, the author has effectively organized the work around those basic questions that must be answered one way or another by means of the structure and functioning of any economic system: What should be produced? How will the goods and services be produced? How will money and the exchange of goods and services be managed? What total production will be realized, and what provision should be made for growth of the economy? Who should get the goods and services produced?

Although there is continual emphasis on the principal institutional characteristics of the economy of the United States and on relationships of economics to public policy, the main theme is elementary analysis: essential vocabulary, concepts, and principles applicable to policy considerations and decisions. The book begins with an overview of economic systems, focusing on the underlying situation of scarcity and, historically and comparatively, on cultural variations in the resultant functions of economizing. These functions, the counterparts of the basic questions (above) that must be answered in any economic system, are treated analytically, largely from the standpoint of a private enterprise system. Three-fourths of the book, between the initial overview and the final chapters on the international economy and the Russian and British systems, is devoted to this analytic interpretation of the functions of the economy in the setting of major problems and issues. The author's presentation of micro and macro concepts and principles, integral to his explanation of the functions of the economy, is clear and careful. His informative surveys of monopoly, labor problems, agricultural problems, and public finance are woven into his treatment of the function of distributing income.

One limitation of the book is inherent in the one-semester course for which it was written: too many topics for the time available (insufficient time for thorough study of a topic and for thinking through the subject matter), inadequate provision for the time-consuming process of learning micro and macro concepts and principles and developing illustrations and applications. Another limitation is characteristic of introductory textbooks: the need for more effectual explanation of the relationships of elementary concepts and principles to public policy. Textbook writers might well develop improved expository techniques for the movement from concepts and principles (or analytic models) to applications involving policy.

It is interesting to note that the author's conception of a rewarding introduction to economics, though designed for college courses, is similar to the conception developed for guidance of the schools by the National Task Force on Economic Education in its report of September 1961. The college textbook simply reflects, and is adjusted to, the character, pace, and intensity of college-level work. The usefulness of the college textbook, however, like

the usefulness of school books and materials, depends not only on its quality but also on how it is used. The Task Force's enjoiner should be underscored, that "we emphasize the importance of teaching that leads students to examine and think through major economic problems for themselves."

JAMES H. STAUSS

Grinnell College

Economics, Measurement, Theories, Case Studies. By GEORGE SOULE, with the assistance of Leland T. Traywick and Francis C. Boddy. New York: Holt, Rinehart and Winston, Inc. Pp. xii, 446. \$5.75.

Professor Soule's book "Economics, Measurements, Theories, Case Studies" is an introductory textbook designed for students of liberal arts. The book is, as indicated by the title, subdivided into three parts. In the first one the student learns in a rudimentary way what a business financial statement, a government's budget, and national income accounts are. In a few pages he gets a quick glimpse at statistical measures, such as simple averages, weighted averages and index numbers. After a warning that statistics should be used with care he is then ready to study the second part.

I had expected, according to the title of the book that this would be "Theories." It is rather, as the author terms it in line with its contents, "How Our Institutions Operate." In fact there is not much theory in this part. A short section deals with the "Theory of Supply and Demand" where the usual intersecting supply and demand curves are shown. An eager student will look in vain however for an explanation of what determines the supply curve of a firm: the book does not include a discussion of marginal cost, and marginal concepts in general. As a consequence such standard problems as the minimum cost point under competition or the differences among competitive, monopolistic and monopoly situations are either not treated or only in an unsatisfactory manner. One of the most important problems in economics, the problem of maximization, is thus not brought into a sharp focus and is largely by-passed.

Another section deals with the "Theories of Money and Income." The author starts out with the quantity theory, which is adequately handled. I found the determination of income somewhat confusing. A student may have difficulties in understanding from the text how a Keynesian system of the *General Theory* type, to which the author refers, works. There is no clear indication how the money supply, interest rates, and investments are related. The student learns that one of Keynes' great contributions in the *General Theory* was to indicate the possibility of a permanent underemployment equilibrium. In this context I think it would have been advisable to mention the existence of a liquidity preference function and discuss a few of its properties. This is not done, and the reader may be left up in the air.

The last part of the book deals with case studies in economics. The problems discussed range over the level of steel prices, an investigation of who the villain is in a cost-push inflation, and the needs of underdeveloped countries.

One cannot, of course, expect that an introductory textbook will set forth

all the finer details of economic theory. A certain amount of rigorous analysis at the elementary level—as contained in some other widely used introductory textbooks—is, however, in my view, desirable and can be readily understood. In this respect Soule's book may be found somewhat disappointing.

A student who works through this volume will get a pretty good idea what our institutions and main economic problems are. He may, on the other hand, feel that he misses a theoretical framework—however simple—which would permit him to put each of the many things he has heard about in a proper place, and which would help him to get a rough idea what has an influence on what.

Soule's approach is basically an institutional one. There are certainly merits in this. In the opinion of this reviewer an introductory textbook should however possess a balance between its institutional and theoretical contents. This balance is missing in this book and may impair its usefulness as a text for beginning students in economics.

KARL W. ROSKAMP

Wayne State University

Price and Allocation Theory; Income and Employment Theory; Related Empirical Studies; History of Economic Thought

Output, Input and Productivity Measurement. National Bureau of Economic Research, Studies in Income and Wealth, Vol. 25. Princeton: Princeton University Press, 1961. Pp. x, 506. \$10.00.

The National Bureau of Economic Research has given producers and users of productivity data yet another reason for being grateful for its efforts. A volume of at least equal scope would be required to review and evaluate the rich contributions of this conference report. It consists of three groups of papers, with comment, covering: (1) Productivity and the Measurement of Real Outputs and Inputs; (2) The Estimation of Real Product in the Economy by Industries; (3) The Estimation of Real Factors Inputs.

The tone of the volume is set in John W. Kendrick's introduction: "... productivity remains one field in which economic statistics have been ahead of theory"; and in Kenneth Boulding's comment that "In all problems of measurement, the fundamental question is, *what questions can be answered better as a result of the measures devised.*"

The first Part opens with an essay by Irving H. Siegel on index design, and is followed by a provocative paper from George Stigler on theoretical aspects of productivity measurement. The three other papers of this Part summarize important collections of natural resources and productivity data. Harold J. Barnett's essay explores changes in natural resource scarcity; and productivity in natural resource industries is analyzed by Neal Potter and Francis T. Christy, Jr. Finally, Leon Greenberg collates the valuable data on productivity from the Bureau of Labor Statistics.

In Part II, V. R. Berlinguette and F. H. Leacy review Canadian experience in real product measurement. Problems of international comparisons of real product are dealt with by Milton Gilbert and Wilfred Beckerman. Two papers

on the United States complete this Part. Real product by industrial sector is the topic for Jack Alterman and Eva E. Jacobs; and Almarin Phillips deals with industry net output estimates.

Kenneth Boulding opens Part III with a lucid discussion of the concept of economic input. Labor input measurement is the special sphere of the following paper by Edward F. Denison. Two contributions deal with problems of measuring capital: concepts of real capital stocks by Richard and Nancy Ruggles; and Daniel Creamer's notes on long-term capital estimates. The final essay of the volume is on factor substitution and the impact of taxation on composition of output.

An able introduction by John W. Kendrick summarizes salient points of the several papers. Altogether, this is distinguished scholarship, and the program committee (John W. Kendrick, Chairman, Harold Barger, T. C. Schelling and Irving H. Siegel) deserves the thanks of the profession.

An interest in "total productivity" and emphasis on accounting categories for measurement pervade much of this work. This is part of the effort to utilize deflated national product as a measure of final physical goods and services. These essays suggest problems attending such efforts beyond those dealt with in this volume.

After the money value of goods has been deflated by a price index, it is assumed that the resulting series measures a changing quantity of goods, however affected by alteration in quality. The dollar of goods, however, represents payment not only for production but also for decision-making services. The latter have grown remarkably as a portion of the total cost of industrial activity. Hence a deflated dollar of goods measures a changing proportion of actual goods and administrative services. The same factor affects international real product comparisons at a single time.

Measuring inputs in accounting categories opens up the problem of coping with inputs that are not readily given money value but are certainly important for variation in productivity levels, however output may be measured. Knowledge is a most important factor in production and its monetary valuation represents a world of unsolved problems. Organization, as in the timing of operations, has a powerful effect on productivity. I have seen productivity raised by 15 per cent in one year in large plants simply by reducing the variability in weekly production rates. The measurement of "organization" as an input is, to my knowledge, still an unsolved problem.

If one takes a cue from the relativism that is underscored by Siegel and Boulding, then the national accounting approach to productivity can be appreciated as especially useful for analysis of distributive shares of income and kindred problems. The development of productivity measures which emphasize physical categories is a more appropriate approach for the diagnosis of productive systems. Aspects of both approaches are intermixed in the papers of this volume. I think more formal relativism in productivity analysis will give strength to the knowledge of the field.

I find that the concluding essay on factor substitution leaves something to be desired. Its conclusion, that wage pressure plays a negligible role in deter-

mining changes in production methods will not stand close scrutiny. The relevant data have not been adequately reviewed.

On the whole this volume makes a series of substantial contributions which will surely encourage new inquiry in this field.

SEYMOUR MELMAN

Columbia University

Stratégie du marché—théorie de la firme et vente sous marque. By MARCEL MICHEL. Paris: Presses Universitaires de France, 1961. Pp. 246. NF 24.00.

In this book on price theory and market strategy the author is primarily concerned with the behavior of commercial intermediaries (retailers in particular) in multiproduct markets operating under conditions of monopolistic competition. He points out that—apart from the applications of the full-cost theory provided by John F. Due and H. Smith, whereby they show the inevitability of retail price stability over the long run, and apart from the explanations of marginalistic demand of intermediaries by E. R. Hawkins—very little has been done in this area. He also suggests that the problem of retail price-fixing by the producer is another important feature requiring analysis for the determination of market strategy. Here he notes the work done by H. Clay, B. S. Yamey, and J. P. de Bodt. Using all of these contributions as a basis, the writer seeks to develop a coherent exposition of the principles which govern selling policy.

He begins by devoting two chapters to the problem of profit maximization where the producer is turning out a trade-mark commodity with no intermediary between himself and the consumer. Various methods of finding the optimum combination of selling price, advertising expenditures, and volume of production are examined. The special price-setting problems of oligopoly are also taken into account, and a formula for determining maximum oligopolistic profit with varying selling programs is considered. Throughout this discussion the writer relies heavily on the contributions of Joel Dean, J. P. de Bodt, R. M. Shone, K. E. Boulding, F. H. Hahn, and N. S. Buchanan. While the analysis is in no sense original, it constitutes a clear and concise synthesis of the various views.

In the third chapter multiproduct output is introduced. Using the principles established by Joan Robinson, the author shows how the producer of a single commodity is encouraged to use several trade-marks and to differentiate prices in order to exploit varying market elasticities. This leads to a discussion of basic product diversification. Output of products where there is interdependence in the demand, and of products where the demands are not interdependent, are considered. He concludes that producers will concentrate on those products which have the least elastic demand, and also on those which will sell at the highest level above marginal cost.

At this point the author pauses to consider whether or not a policy of price differentiation for similar goods sold under various trade-marks is in the public interest. He reaches the conclusion that low-income buyers normally

benefit because of the greater elasticity of their demand, although under special circumstances it is possible for both low-income and high-income buyers to benefit.

Finally, in the fourth and fifth chapters, the retailer as an intermediary is brought into the analysis. Pricing policies on the basis of traditional mark-ups or of oligopolistic consensus are examined and rejected. The thesis of intuitive marginalism, wherein the retailers presume varying elasticities of demand for different commodities, is advanced. The author argues that, if this thesis holds, the marginal revenue curve of each intermediary becomes his demand curve in purchases from his predecessor in the chain of distribution. Thus retail prices become relatively fixed, even though costs of production vary. Also retail price-setting by the manufacturer of a trade-mark commodity is encouraged.

Where all retailers face demands of about the same elasticity, the retail price will normally be that which provides maximum profit for the producer and for each of the intermediaries. But the various retailers usually do not sell to a homogeneous clientele. Retailers who cater to high-income buyers will press for the imposition of minimum retail prices by the manufacturer. If the producer gives way to this argument, he loses the advantage of price differentiation. Moreover, differences in demand elasticities encountered by luxury shops as compared to large-scale distributors are such that a fixed minimum price will be too low for the one and too high for the other. Competitive forces among large-scale distributors will then almost certainly operate to restore price differentiation through discounting. A minimum price simply provides a yardstick for price-cutting, and is disadvantageous for the producer who seeks to impose a retail price at too high a level.

The introduction of distributional intermediaries into price analysis constitutes an important addition to the theory. The assumption of intuitive marginalism upon which the argument is based might be difficult to prove or disprove. Nevertheless, it is implicit in almost all price analysis, and is therefore quite as reasonable in this area as in any other. Certainly the findings supply some answers to problems of selling policy where previously no answers existed.

HENRY GRAYSON

University of Maryland

Keynesian Economics in the Stream of Economic Thought. By HARLAN L. McCracken. Baton Rouge: Louisiana State University Press, 1961. Pp. xv, 201. \$5.00.

In many respects this work on Keynesian economics is a remarkable and rather unique addition to the contributions made these past twenty-five years toward an understanding and explication of *The General Theory of Employment Interest and Money*. As an undoubted tribute to its own intellectual majesty, that product of John Maynard Keynes has been subjected to almost every conceivable type of criticism, most of it along intensive analytic lines. Summarizing with exceptional clarity and insight both the essentials of Keynesianism and the cumulative results of this intensive critical analysis,

Professor McCracken provides an interesting and instructive historical setting for this controversy of a quarter of a century. With it he traces several fundamental Keynesian ideas back to eighteenth and nineteenth century sources and on the basis of his cogent summaries, as well as his own theoretic strictures, projects the subject into the future for a tentative determination of the permanent scientific values of the "New Economics."

Needless to say, those who are emotionally committed either for or against Keynes at this late date will find grounds for objection to this study. To view the work from this insular angle would be both pointless and unconstructive. The author doubtless set a monumental task for himself in attempting a comprehensive appraisal of the meaning, significance, and enduring utilities of Keynesian economic ideas within the broad context of the development of modern economic thought. As professor emeritus and former chairman of the department of economics at Louisiana State University, he brings to bear his accumulated knowledge and wisdom in the pioneering fulfillment of this task. Dedicating the work to the graduate students of his Keynesian seminar, he effectively combines in this study an analytic grasp of Keynes' thought, the perspectives of general theory and business cycle research, and a rich background in the history of economic thought. The book reflects brilliantly these many strains of training and experience.

To be sure, this volume will not be the last of its kind. As the years pass both the intellectual and existential bases for still more objective historico-analytic evaluations of Keynes will be extended, and his ideas and influence will be viewed in a clear light. However, McCracken's contribution represents an important link in the chain of research and judgment that the future will forge further. The outlines of its historico-analytic treatment will undoubtedly serve as the paths for others to develop the subject in still greater detail. And unquestionably its generalizations and interpretations will be accepted or rejected as our vision expands in latitude and scope.

Divided into two parts, the book deals first with the pre-Keynesian economists and then with the Keynesian system of economic thought. One reason for the division is to show what are the new and not-new ideas in the system. The author covers in the first part such topics as Say's law of markets, the critical thought of Malthus, the macroeconomic orientation of Adam Smith, Lord Lauderdale and Bernard Mandeville, the science and art of economics, the role of Richard T. Ely and certain founders of the American Economic Association, and the paramount ideas advanced by John R. Commons. The second part of the book is devoted to the basic principles of the Keynesian system, their applications in the fields of monetary and fiscal policy, the theory of interest and prices, and the future of Keynesian economics. The chapters are well organized and lucidly written. The bibliography is not as extensive as it perhaps should be, but most of the key works are listed.

The author's discussions of Malthus, Lauderdale, and Commons disclose many keen insights and refreshing viewpoints. He makes his major point that ideas of effective demand, macroeconomic analysis, the fallacy of composition, and the impact of expectations on present values are not new with Keynes. His treatment of Malthus and Commons is substantial enough to dissipate

the seeming novelty of some of Keynes' determining ideas. The chapter on Commons is particularly instructive in showing why this outstanding American institutionalist regarded Keynesianism as another managerial school of thought which could breed totalitarian inclinations in thought and behavior. But some of McCracken's observations and generalizations regarding Say's law of markets, Ricardo's thought, and the presumed sterility of classical economic logic can be easily refuted. It is, for example, scarcely impressive to deprecate the logical structure of classical thought in the first part of the book and later to conclude that classical theory comes into its own in re-emerging conditions of brisk economic activity.

In the second part of the book the reader is exposed to a rather stimulating coverage of Keynesian essentials and their qualified applications in economic policy. Although here, too, a number of interpretations concerning the causes of the great depression or the actual impact of Keynesian thinking on the policies of governments may be subject to valid criticism, the author's analysis is more secure. He concentrates on limiting factors in his discussion of monetary and fiscal policies and gives an absorbing account of both factual and theoretic developments following the so-called Keynesian revolution. More emphasis could have been placed on the decelerating effects of increasing consumption upon economic growth and also the usability of Keynesian constructs in conservative thought. Projecting his analysis into the future, McCracken predicts that the Keynesian tenets of effective demand, the consumption function, the multiplier, expectations, and the qualified theory of prices will remain. Slated to evaporate are the theory of the matured economy, overemphasized macroeconomics, lighthearted attitudes toward deficit spending, and the "givens" of monopoly and monopolistic competition.

By virtue of its diverse contents and lucid presentation this work is capable of a wide appeal. Economic and general historians, theorists, students of public finance, money and banking, and labor will find its interrelated subject matter of considerable interest and worth. What's more, it makes for enjoyable reading.

LEV E. DOBRIANSKY

Georgetown University

Malthus & Lauderdale, the Anti-Ricardian Tradition. By MORTON PAGLIN. New York: Augustus M. Kelley, 1961. Pp. 184. \$4.75.

"As presented by Mr. Ricardo, political economy possesses a regularity and simplicity beyond what exists in nature; as exhibited by Mr. Malthus, it is a chaos of original but unconnected elements," Torrens wrote in 1821. Paglin's study affirms the judgment and helps to explain why the world has preferred Ricardo to Malthus, Lauderdale, and those like them. There were other reasons also, according to Paglin. Lauderdale and Malthus were not as persistent, had not an able or industrious coterie, were compromised by their support of agricultural protection, and were hopelessly conservative in their politics.

Economics would have come to its present position more quickly if the anti-Ricardians had been more effectual. Their contributions were substantial.

While Ricardo wanted to explain the distribution of income (which was hardly a critical issue in 1817), Lauderdale investigated the prior question of what income and wealth are, and Malthus' purpose was "attending to facts and experience." Both rejected the labor theory of value and so disencumbered economics of a notion as old as common sense and as undependable. In its place they put supply and demand. They distinguished between demand as a quantity and as a schedule, and Lauderdale had the idea of price elasticity of demand. He avoided Ricardo's error of thinking that wages did not measure the output of labor and Smith's mistake of distinguishing between productive and unproductive labor. Both attended to macroeconomics more than the Ricardians did, Malthus with his celebrated notion of overproduction and Lauderdale in showing the relationship between aggregate demand and fiscal policy. Contemporary economics will quarrel with many of their formulations, but it contains more of their ideas than it does those of Ricardo. In his day Lauderdale was treated indifferently at home, but with respect abroad. He influenced the American, Daniel Raymond, whose principle of policy was brief: "All a legislator has occasion to ascertain, is, whether the nation has full employment, and if not, to furnish it." The method was a discriminating use of the tariff, and Raymond's explanation is an interesting exercise in the economics of development.

Malthus was not ignored. The Ricardians got some of their ideas from his early work, and his later ideas engaged their interest. But they were unpersuaded. His long correspondence with Ricardo is a monument to the persistence and amiability of the two men. Each tried to bring the other to his own views without, it seems, really expecting to succeed. They were like Adams and Jefferson who also were engaged in a notable correspondence at that time and had no more hope of changing each other's mind.

An important part of Paglin's study is the comparison of Malthus' *Essay* on population with his *Principles of Political Economy*. In the former he assumed full employment (and underproduction) and in the latter unemployment and overproduction. The two cannot be reconciled, Paglin explains, by supposing Malthus was writing of the long run in the *Essay* and the short run in the *Principles*, because in fact he made no such time distinction. The inconsistency was an example of the "unconnected" elements in his doctrine. But as Sidney Smith said of him, "I would almost consent to speak as inarticulately if I could think and act as wisely."

Paglin has done well to recall Lauderdale and Malthus to us. A part of his study is necessarily a statement of Ricardo's doctrine, and while meaning to rescue its critics from neglect he seems nearly to have succumbed to it himself. His explanation of Lauderdale's doctrine would have been more instructive if he had included a statement of those portions of Smith's doctrine which Lauderdale disputed. He might also have told us more of Lauderdale's transformation from Jacobin to Tory. It is a little cursory to say that his economic policy reflected the conservative ideas of Burke since Burke was not a conservative in the strict meaning of the word. In any event he did not influence Lauderdale until the latter was past 60. Before that Lauderdale was a champion of *laissez faire* in its most extreme form. For example, he opposed

child labor legislation in 1818 on the grounds that "labour ought to be left free." To say that Malthus' ideas of policy expressed an attachment to a nonindustrial society is to imply that they had more consistency than his positive economics had. Actually he wrote that "the effects of manufactures and commerce on the general state of society are, in the highest degree, beneficial" (*Observations on . . . the Corn Laws*, 1815, p. 31). As a politician he was no more consistent than as an economist. I must object also to the implication that the Ricardians were unqualified free traders. They were not; and Ricardo himself advocated permanent protection to agriculture.

WILLIAM D. GRAMPP

University of Illinois, Chicago

Intermediate Price Theory. By DIRAN BODENHORN. New York: McGraw-Hill Book Co., 1961. Pp. vii, 318. \$6.75.

In the traditional manner, Diran Bodenhorn has compiled a text of standard dimensions dealing deductively with profit maximization and utility maximization in a framework of static, marginalist equilibrium theory. Consistency and determinateness having been dearly purchased, they are displayed tidily, competently and mathematically. Long-run and short-run, competitive and noncompetitive contexts are studiously explored. Limitations of method are confessed but are not permitted to inhibit the familiar transition from "analysis" to "theory" to "applications." Since this is the sort of book that can be done well, it is done rather often; and this specimen of the genre is certainly adequate.

The author says that his book is an "intermediate" text that concentrates on "the proper approach" to price-theory problems. Should a reviewer confine himself to the criteria that would substantiate this claim, or should he measure the performance by standards he considers more valid? If the former, then the book is indeed "intermediate," in the sense that beginners would not tolerate it, and "proper" to the degree that exercise in deductive, axiomatic, stringently abstract reasoning about the implications of self-interested acquisitiveness is proper. On this ground, one would raise only a few objections to the book; *viz.*: Do firms, families, unions and nation states have *self-interest*? Are the tidy tautologies of maximization instructive? Are awkward expositions retrieved by the liberal interspersion of such words as "clearly," "of course," "necessarily," and the like? Why so little use of conditional tense and subjunctive mood in a work so laden with assumptions? Is "economic rent" unambiguously defined on page 290? That sort of thing. If the latter, then I have more to say.

To me the book is entirely elementary, however intimidating to the beginner. (I am thinking of my teacher who said, "Only a coward confines himself to heroic abstraction.") Bodenhorn shows us (as others have) what price theory must be like if it is to be tamed and confined within analogies to plane geometry and the simple differential calculus—just as Walras showed us what an economy would have to be like if it were autonomously and spontaneously to achieve a multidimensional equilibrium.

Since Bodenhorn is doing what has been done (better) before, he should be obligated to infuse into the basic traditional models some of the new wisdom. Why not a word on Löwe's handling of expectations in equilibrium models? On Knight's handling of the variable meaning of "the short run"? On Dean's concepts of profit? On Myrdal's treatment of latent political premises in economic thought? On Koopmans' "shadow prices"? On Graaff's welfare propositions? On Lindblom's "systems mix"? The author enters realms where these insights are pertinent, but scarcely scratches the surface. In intermediate discourse, I think, a talent for abstraction should be wielded with humility; a concern for the limits and dangers of the method is becoming. Each time the tired, traditional material is reworked, more should be assimilated; otherwise everyone's time is wasted.

What makes many texts so arid is the lack of any apparent devotion to the teaching of students. One should not pay \$6.75 to see an author pirouette for his peers. Seeking to gain some understanding of the world in which he lives, the student should object to uninformative and really quite unsophisticated statements about how demand goes downward and to the right, how firms seek out tangencies, and how one thing cuts another from beneath.

A student likewise should not have to wait for an "advanced" text to discover such things as the interdependence and inseparability of "maximum production" and "equitable distribution," or the multiplicity of the supposedly singular "Pareto optimum," or the operational impossibility of identifying the marginal productivity of labor; but after Chapters 17 (Welfare and the Price System) and 19 (Applications to the Labor Market), he must still wait.

A student should be helped early in the game to avoid the value judgment which so often slips in just after the *wertfrei* oath is taken. For example, he should not have one "popular idea" (that teachers are really worth more than they are getting) dismissed as outside the scope of economics, and in the next breath see another popular idea (that the free market has the function of telling the employer what the employee is worth) enthroned as a positive principle. Simple recourse to the value-smuggling word "function" does not make free enterprise a scientific choice nor put an end to the arbitrariness of its "costing" of inputs.

A student at the intermediate level could be told (couldn't he?) that "revealed preference," "disutility of labor" and "hedonistic motivation" do not exhaust the psychological and philosophical aspects of getting a living. True, one is free to abstract from all that cannot be manipulated with mathematical logic; but then one should stay clear of easy "applications." The pious hope that an easy point of departure "usually points in the right direction" mocks the apparent technical rigor of many a text.

Some books are written too soon and are circulated too widely. Although I have no reason to think that the present book is a case in point, some books are written prematurely because of administrative pressure to publish and not primarily to promote learning. For the former type I suggest that only one copy be printed and then impounded in a special library set aside for perishables published in response to the edict of publish or perish. This copy

can be destroyed when the promotion is made. In this way students are spared, one does not read what he will wish he had not, and we diminish the likelihood of denuding our national forests.

DANIEL HALE GRAY

Middlesex County National Bank in Massachusetts

Preistheorie. By KARL BRANDT. Ludwigshafen: Fachverlag für Wirtschaftstheorie und Ökonometrie, 1960. Pp. vii, 208. DM 13.80.

Professor Brandt's book is the first volume in a new German series on economic theory, designed to give the student a concise and rigorous survey of economic principles. The present volume deals with the traditional content of price theory and leaves for later volumes such topics as game theory and operations research. As the author states in the preface, an integration of these topics appears possible only after economists have been more successful in relating an exposition of different market structures with entrepreneurial decision-making and consumer behavior.

The first three chapters discuss the basic problems of price formation. Of special interest is the introduction to the methodology and history of price theory. Brandt distinguishes the historical, the sociological, and the "model-theoretical" approach; the latter alone is said to permit a theoretical understanding of the role of markets and the process of price formation. As should be expected, German and Italian contributions to the historical development of price theory receive more attention than is customary in English and American texts. Modern price theory is traced back to the work of the mercantilists. Verri and Frisi, Canard and Buquoy, as well as J. Becher, are all concerned with establishing a suitable classification of markets. Cournot is credited with founding modern price theory through his successful contrast of price formation in different market structures. Special recognition is given to Auspitz and Lieben for their original approach to the explanation of exchange functions.

The following three chapters take up the processes of price formation under conditions of competition, monopoly, and oligopoly. Here again, the careful references to historical antecedents are impressive. Thus, the concept of price elasticity is illustrated by G. King's observations on crop yields and the price of wheat. Conditions of price stability are discussed under various elasticity assumptions which in turn are related to market structures. Monopoly is defined to include cases of sole transactors on either the supply or the demand side of the market. There follow comments on price formation under "collective monopolies" which originate through horizontal or vertical integration. The discussion of bilateral monopoly summarizes the more extensive treatment given by E. Schneider in his *Introduction to Economic Theory*. The discussion of various oligopoly situations appears particularly well done.

The last three chapters deal with "heteromere" markets, the influence of expectations, and problems of price dynamics. Heteromere markets exist wherever nonprice competition becomes important, illustrated by spatial competition, quality competition with selling costs, polypolistic competition with kinky demand functions. In this general context the author considers the wide

variety of market structures where it becomes impossible to judge "when monopolistic competition shows restrictions harmful to the consumer and when economies of scale with quality competition should be encouraged." This consideration leads to the more general introduction of expectations as they influence market behavior under conditions of uncertainty. Here also are introduced some elements of game theory and operations research, based on the classification of market strategies first propounded by R. Frisch. This line of reasoning leads to a basic distinction between adjustment to given markets and creation of new market structures. Price determination with time lags, but static market structures, is explained by the cobweb theorem. A brief sketch of general equilibrium theory, with an outline of dynamic price changes, concludes the volume. In a book full of historic references it seems strange not to find Schumpeter mentioned in the discussion of competitive dynamics.

Brandt's *Preistheorie* well accomplishes its purpose to provide "a brief introduction to the principles of market and price formation." As such it offers to the German student a good survey of the U.S. literature; its didactic usefulness is enhanced by a German translation of Allen, Morgner and Strotz's *Problems in the Theory of Price* designed to complement this new text. But the book should also be of interest to the U.S. economist looking for a concise outline of recent German literature. For purposes of reference the book would gain from the addition of an index; also the bibliography could have perhaps been arranged more usefully by topics. Yet these are minor faults which detract little from the merits of a book written with clearness and precision. We look forward to future volumes in this promising German series on economic theory and econometrics.

WERNER HOCHWALD

Washington University

Economics and American Industry. By LEONARD W. WEISS. New York: John Wiley, 1961. Pp. xi, 548. \$7.50.

Professor Weiss has undertaken the difficult task of attempting to combine in a single, intermediate-level text a systematic treatment of price and distribution theory and several case studies of American industries. For those who are interested primarily in a comprehensive, cohesive, and self-contained micro-theory text, or primarily in a thorough case-study analysis of American industries, the results will seem disappointing. However, for those interested in a text providing the essentials of the theory of the firm, along with illustrations of important aspects of economic theory and public policy, and realistic qualifications of theory as it is taught in undergraduate courses, this book will be a welcome addition.

The general organization of the book is traditional in the sense of treating in order pure competition, followed by pure monopoly, oligopoly, and monopolistic competition. Each case study includes a discussion of the standard theory and an analysis of industry cases in terms of history, structure, and performance, but not necessarily in that order. In the early chapters Weiss moves from the theory to actual case data (e.g., pure competition), providing

a thorough groundwork in cost and demand theory and its usefulness in appraising the problems and policy issues in agriculture and textiles. In the cases of monopoly, oligopoly, and monopolistic competition, Weiss works initially from the empirical data back to the theory, always attempting to evaluate realistically observed market behavior. Proceeding in this way, Weiss succeeds in developing theoretical concepts to a sufficient degree of sophistication so that they become meaningful, understandable, and useful to the student.

In addition to industry studies of agriculture, textiles, aluminum, steel and automobiles, the book includes a fairly detailed and interesting analysis of regulated industries (electric power), retailing, and factor pricing (steelworkers). This last chapter is a useful addition, but falls short of the author's early promise of "a systematic presentation of . . . distribution theory" (p. v.).

The use of numerous graphic illustrations and statistics on prices, output, profits, productivity, makes the book interesting reading and provides ample material for discussion and analysis of the case studies. Weiss writes easily and lucidly, which makes the book both palatable and teachable.

On questions of public policy, Weiss is generally quite circumspect in his evaluation of the performance of individual industries and broad industry groupings. As a result, his analysis does not always come to grips with the public-policy issues arising out of abusive, predatory, and exclusionary behavior of particular firms. For example, in discussing aluminum he makes several observations that seemingly overlook facts brought out in the record of the antitrust case. ". . . Alcoa had to compete with other materials such as steel, copper, and magnesium. The difference between such competition and that of Fords with Chryslers and Buicks is only a matter of degree" (p. 165). "If Alcoa did have any deliberate policy of exclusion, it lay in its expansion" (p. 180); and "Monopoly might not have been inevitable in the aluminum industry to start with, but Alcoa, once established, was able to hang on to its exclusive position while usually staying well within the bounds of normal business ethics" (p. 181). Considering Alcoa's efforts to retard magnesium's development under well-disciplined control through cartel agreements with Dow and I. G. Farben, its price squeezes on competitors and its other practices designed to maintain its monopoly position, one must pause before accepting such observations at their face value. Similar observations might be made about the attention given to market conduct in steel and autos.

The final chapter is devoted to an analysis of the structure and performance of U.S. industry generally. Using earlier studies as well as some original statistical tests applied to broad industry groupings, Weiss examines the relationships between structure (concentration) on the one hand, and profits, efficiency, selling expense, and progressiveness on the other. His general conclusions regarding industry performance are that: (1) High profits and high wages are associated with high industry concentration with the result that an estimated 8 or 9 per cent of national income (or roughly \$40 billion) consists of "excess" profits and "excess" wages. (2) Expensive advertising, which is of little or no direct social value, seems to be primarily a problem connected with certain concentrated industries. (3) While gains in efficiency from concentration may make up for waste in some cases, in a larger number of

cases we can have the advantages of large scale and competition. (4) On the average, concentrated industries do not seem to do any better (or worse) than the competitive ones in the rate at which they improve efficiency. (5) Economic concentration is one of the important barriers to movement of factors of production and probably helps perpetuate the inequality of income. (6) The concentrated character of certain industries has contributed to the creeping inflation since the mid-1950's. While these findings are neither new nor startling, they provide a much broader base against which the appropriateness of the conclusions of the case studies can be tested.

In short, Weiss has done a very creditable job of attempting to reconcile theory with industry behavior. Those who have been looking for an intermediate-level text that is concerned with making economic analysis both useful and interesting to the student will be well-advised to give this text careful consideration.

ROBERT F. LANZILLOTTI

Michigan State University

Economic History; Economic Development; National Economies

Narodnoie bogatstvo i narodnokhoziaistvennoie nakoplenie predrevolutsionnoi Rossii. By ALBERT L. VAINSHTEIN. (National Wealth and Accumulation in Prerevolutionary Russia.) Moscow: Gospolitizdat, 1960. Pp. 483.

The bulk of this book (Part II, pp. 149-366) is devoted to a detailed estimate of material reproducible wealth, located in the Russian Empire (ex. Finland) at the end of calendar year 1913, with parallel sets for totals and components within the pre-1939 boundaries of the USSR. The stock estimates, on a depreciated basis, are supplemented by approximations to capital accumulation for 1913, and to average volume for 1911-13. In the last Part (III, pp. 367-446), we find an extensive summary in which total domestically located wealth, and its accumulation, are distributed among various user sectors and by type of capital good (buildings and plants, other construction, equipment, livestock etc.). In the last chapter (pp. 426-45) an estimate is also provided of net foreign indebtedness of Russia at the end of 1913, which can be subtracted from total domestic wealth to derive national wealth. The first Part (I, pp. 15-146) is a lengthy review of conceptual and methodological questions in the literature; but it fails to cover many of the recent writings, and to a reader familiar with the field it is of limited value except for the references to the Soviet literature and to earlier estimates of wealth in pre-revolutionary Russia.

The presentation is sufficiently detailed so that the user can omit or include various components (consumer goods in hands of households, military items, monetary metals, etc.), depending upon the concept which he wishes to follow. The user classification, distinguishing some fourteen groups, is rather mixed, reflecting not so much the importance of the user-groups as the exigencies of estimation; but agriculture, industry (total), and the government sectors can be distinguished, as well as the several transportation utilities. The underlying sources are fire insurance data (accounting for

roughly half of the total), budget inquiries (largely for the agricultural sector), special reports and accounts of the government-owned or -controlled utilities, city governments, and, of course, the usual product of the governmental statistical service. This reviewer, not being familiar with the primary statistics for prerevolutionary Russia, is not capable of judging how fully the available data were exploited and how judiciously the material was used. But, on the evidence in the book, a long and consistent effort appears to have been made to use a wide variety of data and to cover explicitly all significant components of material reproducible wealth within the country.

The estimates of capital accumulation are less securely founded than those of capital stock. The former are available in the fullest detail for 1913 alone; but even those for 1911-13 cover a period that, according to the author's comments (p. 150), represent an unusually favorable experience. At any rate, the over-all magnitude of the accumulation (or net domestic capital formation) totals raises questions that are not raised by the capital stock figures. The latter, excluding consumer goods in the households and military items, amounted to 53 billion roubles (pp. 368-70); the national income for the period, cited by Strumilin (Foreword, p. 8), is set at 16.4 billion. This yields a capital stock-output ratio of 3.2; or allowing for a possible adjustment of the denominator, which probably relates to material product, of close to 3—a ratio within the range of those shown for a number of other countries. But average capital accumulation over 1911-13, again omitting consumer goods and military items, is estimated at 2.44 billion roubles (pp. 417-18), or 15 per cent of the national income total cited. Even allowing for a reduction by about a tenth for the omission in the denominator of services not embodied in commodities, the net capital formation proportion is far too high, particularly for a country at the low level of per capita income of Russia before the First World War. The same question arises when we compare the rate of growth of national wealth, of 4.9 to 5 per cent, shown in the book, with the rate of growth of total agricultural and industrial output for long periods preceding 1913 (estimated at between $2\frac{1}{4}$ and $2\frac{3}{4}$ per cent per year by Raymond W. Goldsmith; see his "The Economic Growth of Tsarist Russia," in *Economic Development and Cultural Change*, April 1961, 9, 441-75, particularly pp. 472-73). It is unlikely that the long-term growth of national product in Russia before the First World War was at the rate of 4 to 5 per cent per year suggested by a combination of a net capital formation proportion of $13\frac{1}{2}$ to 15 per cent and a capital-output ratio of 3 to 3.2; nor that this latter ratio was at such low levels in the earlier decades as to make the high capital formation proportion shown for 1911-13 a plausible approximation to long-term levels.

It is curious that Strumilin, in his foreword, refers to a past controversy concerning, among other items, the prerevolutionary rates of capital accumulation (in 1927, in his own attack on Kondratiev); notes that the estimate of this rate at $8\frac{1}{2}$ per cent of national income was criticized by economists associated with the Gosplan as far too low; and welcomes Vainshtein's upward revision of the author's own, earlier, much lower figure. In the light of these comments, it is interesting to note that the author himself makes no compari-

sons of capital accumulation with national income (this is done only in Strumilin's rather contentious foreword); nor does he examine the level of the implied net capital formation proportion with that in other countries and consider the questions that would have arisen as a result of such comparisons.

But these strictures, relating to the estimates of capital accumulation, do not bear upon the measures of capital stock, and should not lead to a neglect of the significant contribution made by the volume. It is clearly of wide reference value to readers interested in the economic history of Russia and of the USSR, and in the magnitude of national wealth, in its relation to national income and its components, in the process of economic growth.

SIMON KUZNETS

Harvard University

Industry Comes of Age: Business, Labor, and Public Policy, 1860-1897. By EDWARD C. KIRKLAND. New York: Holt, Rinehart, and Winston, 1961. Pp. xv, 445. \$7.50.

This is Volume VI in the Rinehart series on the economic history of the United States, and the seventh to be published of nine projected volumes. Paralleling Fred A. Shannon's *The Farmer's Last Frontier* (Vol. V in the series) in covering the last half of the nineteenth century, Kirkland's work treats business cycles, banking and finance, railroads, natural resources, domestic and foreign trade, tariffs and patents, urbanization, industrialization, labor, and government policy. The title and subtitle, although seemingly narrower than the scope of the book, nevertheless correctly indicate its emphasis.

Anyone who has met Kirkland will recognize this as his book. The twinkle in his eye and the wry wit of his discourse cannot conceal the seriousness of his purpose and the depth of his scholarship. The aptly turned phrase, the appropriate incident, the colorful quotation, the witty comment appear page after page. As a consequence, this is a readable and enjoyable book.

These stylistic pleasures are not mere surface phenomena, sugar-coating a mass of fact and analysis. It is said that style is the man; in this case style is the method. Kirkland has chosen: "to find out how the period actually looked to those who participated in its activities: business men, labor leaders, and politicians." He approaches his subject neither through statistics nor through theories of economic growth, but through thoughts and consequently words of men of the time.

Style and method are in turn reflections of an individual point of view. Opinions of "those who participated" are preferred to observations of on-lookers. Businessmen are "struggling with might and main to rationalize business, to control its disorderliness, and to make their decisions stick." Reformers on the other hand "describe the era by innuendo if not by direct assertion, as one crawling with corruption," a view which "stems from the human tendency in defeat to cry foul play."

This point of view issues in judgments running counter to many received opinions. Kirkland regards as false or unproven assertions that competition declined, that the rich got richer and the poor got poorer, that unbridled

materialism reigned, that corruption was the rule of the day. These charges, not without influence today, are characterized as the exaggerations of reformers such as ex-journalist Henry Demarest Lloyd whose *Wealth Against Commonwealth* was a "fantasy."

Kirkland's conclusions are always his own. Impressively supported by contemporary quotations, they are frequently startling, most often interesting, and almost always worthy of serious attention. His skillful dissection of the classics of reform (Bellamy, Lloyd, and George) and his analysis of their popularity are useful antidotes to frequent uncritical acceptance. His demonstration that reformers and labor leaders shared fundamental values with the businessmen they castigated is a significant contribution. His characterization of cities as "the new generative factor" in the U.S. economy of the late nineteenth century is the key to one of the finest chapters.

Although Kirkland is sparing in his use of statistical data and economical in his presentation of event and organization, this follows from his choice of another approach, another style. Footnotes and bibliography provide those interested in pursuing detailed fact with plentiful material.

Industry Comes of Age is a personal book. Personal because of the materials it employs, and personal because it is so uniquely Edward Kirkland's. On both counts, it is an interesting and important work.

J. WILLIAM FREDRICKSON

North Park College

The Birth of Western Economy: Economic Aspects of the Dark Ages. By ROBERT LATOUCHE. New York: Barnes & Noble Inc., 1961. Pp. xviii, 341. \$7.50.

Although this book deals with a remote period of history, it is of greater relevance to current issues than one would suspect from the title. Instead of exploring the prerequisites of economic growth, it deals with the phenomenon of economic decline and shows what happens when the levers of command fall into the hands of barbarians unable to operate a complex economic system. The machine soon stalls with the result that both output and standard of living suffer a catastrophic setback. This is what happened in the Dark Ages and is occurring again in certain areas of Africa where there is a lack of personnel trained to assume command either in government or in business. Although history never repeats itself, similar conditions are bound to produce similar results. The distressing fact is that humanity does not learn from the lessons of history.

Latouche rejects Pirenne's thesis according to which the Saracen conquest of North Africa and Spain, rather than the barbarian invasions, destroyed the unity of the Mediterranean world and led to the breakdown of Roman civilization. Neither does he adopt the views of Alfred Dopsch, who contends that there was no decline, because the German tribes had reached an advanced stage of civilization when they settled within the Roman empire. In Latouche's opinion, there was gradual deterioration which had already started before the German invasions and received from them a new impetus. Under the inefficient rule of the Merovingians, conditions went from bad to

worse; town life went into an eclipse, roads fell into disrepair, trade shrank in volume, currency was steadily debased, and taxes ceased to be collected, with the result that the king had to live on the product of his own estates. The reign of Charlemagne was only "a temporary restoration" followed by a new succession of upheavals and catastrophes.

It is regrettable that Latouche deliberately excludes any discussion of Italy, which, he claims, deserves a separate study. Nevertheless, this gap detracts from the value of the book as a synthesis on the rebirth of western Europe. The revival of trade and the resurgence of town life occurred in Italy earlier than in Germany or France. Some even argue that there was no breach of continuity. This may be true in certain cases—Pavia and Lucca, for example—and not in others: Venice was a new settlement and Ostia was wiped off the map. Rome itself never recovered from the sack of 455 and the popes lived for centuries surrounded by the ruins of imperial Rome.

The author is well aware of the controversial character of his subject. No statistical data of any sort are available and textual, archeological, and numismatic evidence has given rise to widely varying interpretations. One of the main merits of the book is that the author cautiously refrains from speculation and does not build an attractive hypothesis based on the shaky foundation of inadequate evidence. History does not rest on assumptions but on facts.

RAYMOND DE ROOVER

Brooklyn College

Equilibrium and Growth in the World Economy. By RAGNAR NURKSE. Edited by Gottfried Haberler and Robert M. Stern, with an introduction by Gottfried Haberler. Cambridge: Harvard University Press, 1961. Pp. xiii, 380. \$7.50.

Ragnar Nurkse published only one book in English under his name during his lifetime, the famous *Problems of Capital Formation in Underdeveloped Countries*. His many articles were widely scattered throughout several countries and languages, some of them in journals or symposia that do not come automatically into the hands of all members of the profession. Economists whose interests did not coincide closely with Nurkse's could easily have failed to appreciate the quantity and quality of Nurkse's contribution to economic thought. The collection of essays under review is therefore particularly welcome because it affords easier access to Nurkse's ideas. By the same token it heightens the sense of loss to the profession through so early a death of a man with so keen and original a mind, so rare a talent for blending history, statistics, and theory into a meaningful whole.

Collections of essays are usually difficult to review, since they seldom carry a connected theme that can be isolated for special comment. The present volume is no exception to the rule. The essays selected concentrate mainly on investment, trade and economic development, but they cover a wide range of facts and analysis. The reviewer's chief reaction to the two prewar essays, which reflect Nurkse's Vienna training and the then current interest in the Austrian theory of capital, was "thank God we are through

with that." Even here, however, Nurkse managed to display his independence of thought. He insists (as the reviewer did much later) that cycles and trends have to be analyzed together, and also contends that the structure of production is an important aspect of the business cycle even though the "linear" structure envisaged by the Austrians must be rejected.

The first "Keynesian" essay also seems rather dated, with its defense of Keynesian economics against accusations of nationalism and its discussion of "Stabilisation Fund vs. Clearings Union" proposals and of the proposed charter of the International Trade Organization. The following chapter is also concerned with the system implicit in the Bretton Woods agreements and the proposed ITO, but takes on more permanent interest from Nurkse's defense of a buffer stocks scheme for commodity stabilization and his suggestion for countercyclical timing of foreign investment. His "New Look at the Dollar Problem" (1953) warns against regarding the closing of the dollar gap as a return to "fundamental equilibrium," applies the "demonstration effect" concept to the whole of United States trade, and expresses his preference for capital exports over Harrod's proposal for a higher price of gold.

Chapter 6 is devoted to "Period Analysis and Inventory Cycles." It makes one wish that Nurkse had written more on economic fluctuations. This essay is the second longest in the book and much too tightly reasoned to be dissected. In any case it is rather unrelated to the other essays in the volume.

The remaining essays, more than half the book, were all written between 1956 and Nurkse's death, and are all concerned with investment, trade, and economic growth. The first of this integrated group of articles demonstrates the uniqueness of nineteenth-century investment experience, and the impossibility of using it as a guide for investment policy in the twentieth. If the United States were to devote the same proportion of her national income to foreign investment, net capital exports would range from \$12 to \$20 billion annually—"almost absurdly large" figures. The investment went to "regions of recent settlement," totally different from the underdeveloped countries of today. Today capital flows must be a substitute for, rather than a complement of, international movements of people. Most of the United Kingdom's investment went into social overhead capital, especially railways. In contrast to U.S. foreign direct investment, which creates economic and social dualism, U.K. investment was of a portfolio nature and much of it went to governments. Nurkse ends this chapter with a plea for generous foreign aid.

Chapter 8 is the longest in the book—70 pages—and is devoted to the British balance of payments problem in the decade following the Second World War. It is the "right" kind of economic history, selecting and marshalling facts to fit into a clearly defined analytical framework. He makes telling use of the simple $\text{Exports} - \text{Imports} = \text{Income} - \text{Expenditures}$ formula, and demonstrates that external imbalance reflects excessive internal expenditure—not, as Harrod would have it, excessive investment. Devaluation is a cure for imbalance only if it brings a sufficient cut in domestic spending, which it may not do. The best cure for external imbalance is a highly de-

veloped and currently expanding economy. He makes the astute observation that statistically falling capital-output ratios may not reflect "declining importance of capital," but rather fuller employment of labor and fuller utilization of social overhead capital.

Nurkse's "Reflections on India's Development Plan" (1957) is the most disappointing chapter in the book. It is really a review article based on Vakil and Brahmanand's *Planning for an Expanding Economy* (which has been much more astutely reviewed by William Malenbaum [*Jour. Pol. Econ.*, Oct. 1957, 65, 453]); it is slight and betrays a lack of genuine "feel" for the Indian situation.

Most readers, I suspect, will find the last two chapters most interesting: *Balanced and Unbalanced Growth* (1957) and the Wicksell lectures on *Patterns of Trade and Development* (1959). There is much in these chapters that pleases the reviewer. Development policy cannot be simply an optimal adaptation to existing conditions, including existing factor-proportions; it is not easy to say whether capital or labor is more scarce in underdeveloped countries; the balanced-growth doctrine "is an exercise with unlimited supplies of capital"; balanced growth is related to the classical law of markets—supply creates its own demand if supply is properly distributed among different commodities; it is essential to distinguish between marketable surplus and investable surplus of the farm sector; development of import-replacing industries does not mean autarchy; expanding social overhead capital in advance of needs makes good sense, but carries with it the danger of "Hayekian" crises and creates special needs for capital which are not being fully met by the World Bank and Eximbank. Nurkse's afterthoughts on balanced growth are also of great interest. The notion, he says, is confined to the sphere of directly productive investment, and does not apply to social overhead capital. It is in any case necessary only if export demand is not sufficiently expanding. It is important to distinguish balanced growth as a method and as a goal; even zigzag growth must have balance as an ultimate aim.

In the Wicksell lectures Nurkse returns to his theme of the contrast between nineteenth century and mid-twentieth century patterns of trade, and quotes once again the Marshall dictum, "the causes which determine the economic progress of nations belong to the study of international trade," a phrase of which Nurkse seemed very fond. Once again he underlines the differences between the U.S. position in world markets today and that of the United Kingdom a century ago. He explains why foreign trade is no longer a reliable "engine of growth," and makes the case for development with output "diversified in accordance with domestic elasticities of demand so as to provide markets for each other locally."

The reviewer can find little with which to quarrel in this volume. Nurkse argues (p. 263) that social overhead facilities should be able to pay their way eventually or "there has been a waste of resources." Why? May not marginal cost equal price at a point where average cost is below price? His description of agriculture in underdeveloped countries as "conservative, sometimes feudal, always tradition-bound, passive and noncapitalist" hardly fits

rubber, copra, sugar, tobacco, tea and coffee plantations in the countries the reviewer knows best. But these are quibbles. Taken as a whole this book is a splendid monument to a distinguished economist.

BENJAMIN HIGGINS

University of Texas

Ensayos sobre desarrollo económico. By NICHOLAS KALDOR. Mexico: CEMLA (Center of Latin American Monetary Studies), 1961. Pp. 134.

This small book contains a series of lectures on economic development delivered at the Center of Latin American Monetary Studies in Mexico City in the summer of 1960. The topics of the lectures were: theories of economic growth; policies of economic development; inflation and economic development; taxation and economic development. As may be expected from Kaldor there are in each chapter interesting findings which invite comments.

In the two lectures dealing with theories of economic growth Kaldor stresses the importance of technical dynamism for economic development and concludes that the most important factor determining the rhythm of economic growth is the capacity of an economy to absorb technical change. He believes that the neoclassical school assigns excessive importance to poverty, to lack of natural resources. The author feels that in every underdeveloped country adequate economic policies could lead to accumulation of capital and to technical dynamism.

The views expressed by Kaldor in these chapters are almost identical with those contained in his recently published *Essays on Economic Stability and Growth* (Part III) where the author's lectures at Milan (1954), Peking (1956), and an article from the *Economic Journal* (December 1957) were reproduced. There he wrote: "... the prime mover in the process of economic growth is the readiness to absorb technical change combined with the willingness to invest capital in business ventures" (p. 270).

With regard to the undeveloped countries Kaldor maintains that the real, critical problem is a low rate of dynamism in certain key sectors of the economy which handicaps the growth of the more dynamic sectors. While in principle agreeing with his views one might suggest a comparison of the rate of growth of two countries, both enjoying technical dynamism but differing greatly in resources endowment. Would the rate of growth not be faster in the better endowed country, and furthermore, would not a more prominent role be assigned to capital accumulation when development has reached a more advanced stage?

In discussing policies for promoting economic development the author points out that sustained progress requires various complementary sectors to grow in a certain harmony. Undoubtedly industrial expansion will be limited unless there is an adequate expansion of agricultural production. As one cannot expect that spontaneous forces will secure an adequate rate of sustained growth Kaldor recommends the following government programs: secure an ample supply of social capital, particularly in education; promote increased productivity in agriculture, along with, if necessary, agrarian reform; stimulate, through government-owned or mixed enterprises, the estab-

lishment of basic industries (steel, cement, machine building) or industries with good export prospects. The author suggests that such industries should be expanded at a disproportionate rate to make possible a satisfactory rate of balanced expansion at a later stage.

These recommendations are suitable for the majority of underdeveloped nations except for the emphasis on development with unbalanced growth. Kaldor in a somewhat qualified manner has joined the growing number of economists who favor this type of development. This reviewer believes that more studies are necessary before a general conclusion may be warranted. Recent developments in some Latin American countries appear to support the author's opinion. However, the same cannot be said of experiences in Pakistan and Burma where industrialization was pushed ahead without proper attention to agriculture. A thorough scrutiny of the second five-year plan in India must also be made before assessing the favorable and unfavorable effects of unbalanced growth in India during this period when agriculture did not nearly keep pace with industrial expansion.

Very interesting is Kaldor's discussion concerning the positive and negative effects of inflation as a source of financing development. One can agree with him that in certain circumstances progress initiated by inflation is preferable to stagnation, and also that inflation as an instrument promoting economic development should be compared with other methods available to achieve the same objectives. The author examines the two phases of inflation. During the first phase profits rise more than wages and other costs, and thus accumulation of capital is accelerated except when conspicuous consumption increases greatly; in the second stage the situation is reversed and stable conditions can hardly be established without deflation and unemployment. Brazil is cited as an example of inflation where the investment-boom phase was maintained successfully, as against Chile where inflation resulted in a reduction of the gross rate of investment. Studies in some other countries not mentioned by Kaldor show that huge profits made expansion of industries possible, but because of inadequate increase of wages and salaries the market for newly manufactured goods lagged behind production.

Kaldor concludes that as a whole fiscal policy is much superior to inflation as an instrument for mobilization of resources for development. He makes a good point in saying that even the most stagnant underdeveloped countries have unused saving potential which is much greater than the real saving and which if mobilized would suffice to support higher rates of economic progress. However, how long will it take to change people's habits of investing in jewelry and of engaging in disproportionate spending on weddings, funerals, and similar occasions? According to the author fiscal policy should make a revenue surplus possible which would be available for investment. This could be achieved through a system of progressive personal taxation administered by an elite corps of civil servants paid as well as businessmen are.

The author refers to India (and Ceylon) as countries which introduced tax reforms suggested by him, but all taxes which were introduced on Kaldor's recommendation in India (the expenditure tax, annual wealth tax, and gift tax) yielded only about two per cent of the rp.6500 mil. of tax revenue of the

Central Government. The annual accumulation of the provident funds amounted to more than six times the sum of receipts from the three new taxes. Furthermore no revenue surplus was generated in India which could help finance investment.

The trend of public expenditures was not properly assessed by Kaldor. While substantially higher amounts of personal taxes could without doubt be collected, particularly in many Latin American countries, government expenditures in the developing countries have shown a steady upward trend which will continue for some time. A country-by-country analysis might show where a revenue surplus could be established, at what stage of development, with what prospect of continuing for a number of years, on the assumption that current expenditures needed for development are met from revenue.

In discussing sources of financing Kaldor deals with retained earnings (self-financing), expansion of bank credit (including inflation), and revenue surplus. Not mentioned are savings accumulated at financial institutions which are available for investment. Yet transferred savings have been playing a major role in a number of countries with contractual saving growing faster than voluntary saving. Latin America would not be—with a few exceptions—a good example to illustrate the growing role of this source of funds for investment.

As indicated in this review a number of interesting issues are discussed in Kaldor's book which should stimulate further research and discussion.

ANTONIN BASCH

University of Michigan

Technique of Planning for Accelerated Economic Growth of Underdeveloped Countries. By S. S. WAGLE. Bombay, India: Vora & Co., 1961. Pp. 296. Rs 12.

The high level of theoretical analysis in this work is a credit not only to the writer but to the training he received at Harvard and Bombay universities, both of which awarded him a Ph.D. degree. The approach is that of contemporary welfare economics, all alternatives of economic development being subjected to the test of social costs versus social benefits.

Mr. Wagle demonstrates that the microeconomic approach in terms of profit maximization and an equilibrium allocation of resources will not produce optimum growth in underdeveloped economies. Producers and consumers are not distinctly separated from each other, since production for self-consumption is dominant and factors of production are not substitutable for each other at increasing rates. Indivisibilities and market imperfections intervene, returns to scale increase in the initial organization of basic industries, and income distribution is even more skewed than in advanced economies. Planning by government is essential.

Private marginal productivity of capital is lower than social marginal productivity, the author notes, and public investment may produce external economies and raise the marginal efficiency of capital for private investors.

Most of the significant recent contributions of economists to development

theory have been well tied together here in an integrated theory that should be of service to both planners and economic analysts. The author considers the optimum rate of investment, how the necessary savings can be obtained, resource mobilization, how to accelerate capital formation, the relation of productivity to wage and other factor payments, the problem of sectoral balance, and location of industries in varying orientations to resources and markets. Especially suggestive is the treatment of choice of project and technique, where social costs and benefits are carefully computed in some detail. More capital-intensive techniques should be employed, the author says, when variable costs form a substantial part of the average cost of output, and more labor-intensive techniques should be used when overhead costs are high, especially "in case of projects which may be termed as social overheads of economic development."

The book concludes with a discussion of the problem of regulation and control of prices. Noting the divergence between demand and supply that is an inevitable consequence of any capital-deepening process of growth, Mr. Wagle suggests that "price controls should precede wage controls in the initial stages." Rationing of necessities must supplement price controls, he says; and he demonstrates with indifference curves why he finds rationing superior from a welfare point of view to indirect taxation, which in turn is better than income taxation. Generalizing from Soviet experience, he concludes that "the usual wage functions of organized trade unions are steadily taken over by state authorities in order to regulate economic incentives for accelerating capital formation."

The style and editing of the book are somewhat uneven but it is always possible to discern the theory through the rhetoric.

ROLAND GIBSON

Washington College

Teorija privrednog razvoja u socializmu. (The Theory of Economic Development Under Socialism.) By RADMILA STOJANOVIC. Belgrade: University of Belgrade Press, 1960. Pp. 321.

Historians of economic thought will consider it important that the University of Belgrade has adopted this text. It contains a critical review of both Western and Soviet literature; particular emphasis is given to the concept of "model," and to the symbolic formulation of the content of the model; and the notion is developed that the precise numerical values assigned to the parameters of a model may be as important as the selection of the parameters. The distinction between "Marxist" and "bourgeois" is made, but since the author is Yugoslav and not Soviet he can imply that within either category some work is better than other.

From this distance, it is not easy to state whether the technical simplicity of the treatment is due to the level of preparation of Yugoslav students; or whether the need to equate precisely the relatively simple econometrics of the Soviet bloc with the relative complexity of the Harrod-Domar model precludes the more intensive exploration of what is implied by the various models. If the latter is true, much more interesting work will become possible

if Kantorovich and his Soviet followers are allowed to publish in the future.

In any case, this book illustrates most interestingly the perennial problem of intellectual development: does it reflect the need for Yugoslav economics to solve analytical problems, which are the result of human thought and thus cross national boundaries and even the Iron Curtain; or does it reflect the Yugoslav balance of payments, in which contributions from Washington and Moscow must be carefully equated and apportioned? It is too bad that language difficulties will keep it from being more accessible to a wider group of the profession in the United States.

EDWARD AMES

Purdue University

Canadian Economic Policy. By T. N. BREWIS, H. E. ENGLISH, ANTHONY SCOTT, and PAULIN JEWITT, with a statistical appendix by J. E. GANDER. Toronto: The Macmillan Company of Canada, Ltd., 1961. Pp. xv, 365. \$6.50.

This book is designed to provide a comprehensive review of Canadian government policy in major economic fields since the 1930's and to explain how ordinary economic theories help guide policy-making in a free enterprise economy.

The work is divided into four sections. Part I, Resource Allocation and Government Policy, is concerned with the current pattern of resource allocation, the longer-run problem of economic growth, and the impact of government policy on the use of resources. The examination begins with the general principle that the consumer is "King," and that the price system in a competitive economy tends to serve his best interest by assuring the most efficient use of resources. From here the reader is guided through the deviations from this ideal situation, where degrees of competitiveness vary, and where supply and demand conditions are altered by government decisions. The authors then consider appropriate government policy to reduce this gap between ideal and actual, with specific reference to Canadian legislation. Consideration is also given to public ownership and various types of regulation of the "natural" monopolies.

In addition, capital formation is discussed in relation to economic growth. The sources of funds available for capital expenditures and the factors which tend to influence their supply are discussed. Individual saving is compared with cooperate saving and government allocation for capital expenditures. Some concepts of "ideal" growth rates and the effects of certain government policies on these rates are considered.

The second part, Economic Stability and Government Policy, reviews postwar changes in policies and techniques to stabilize the economy. The authors begin with a discussion of the changing concepts of monetary, fiscal and employment policies by considering the influence of Keynes in the development, during the 1930's, of the concept of a "compensatory" budget and a "cheap money" policy to assure high levels of employment. Many of these financial policies were continued during the Second World War and

were carried forward by the Canadian government into the postwar period. The gradual return to more orthodox financial policies—more flexible monetary policies and a “stabilizing” budget policy—grew out of the experience during the postwar period both in and outside Canada.

The changing techniques of monetary controls during the past decade are also discussed. These include the use of moral suasion in the form of voluntary agreements between the central bank and commercial banks (such as the use of a liquidity as well as a cash reserve ratio), and the introduction of a “fluctuating” exchange rate and a “fluctuating” discount rate. Other financial techniques to permit more flexible countercyclical policies are also introduced, such as government mortgage lending activities. Moreover, various techniques of economic forecasting are examined, including the advantages and shortfalls of each and the consequent difficulties in determining appropriate policy measures.

Section III shifts to a discussion of Economic Welfare and International Aspects of Policy. The theoretical difficulties of determining the welfare aspects of certain policy goals and possible conflicts among various objectives are considered.

On the international aspects of Canadian policy, the book surveys developments which led to current Canadian views on trade and foreign capital movements, and to policy decisions in these fields. The authors trace the changing conditions which were responsible for the increasing reliance upon U.S. markets for Canadian exports over the past 30 years, and the resultant sensitivity of the Canadian economy to both economic fluctuations in this country and the large flows of capital from the United States. The composition of Canada's exports and imports and the problems which Canadians face as a result of a comparative advantage in raw material and agricultural goods are also discussed here.

The fourth section on Policy Formation deals with the political and administrative aspects of Canadian policy-making. It includes a discussion of the division of power and responsibility between the federal and provincial governments, a historical survey of the trend toward stronger federal powers, and a discussion of how policy-making takes place in Canada and how the economic and political interests of various geographic regions and economic groups are reconciled in policy formulation.

From the contents and arrangement of the book it is difficult to determine what group of readers the authors intended to reach. There is a lack of symmetry in the treatment given to the subject matter in the various sections of the book, which seems to reflect differing aims of the various writers. The trained economist will find some parts of the work overly concentrated on a general review of elementary economic theory. Moreover, the reader who wishes a review and understanding of Canadian policy developments will find the book somewhat lacking in documentation.

Perhaps the book will prove most useful in providing the student of Canadian economics with a description of Canadian economic policy developments. It will also provide him with a discussion of the interrelations of

economic theory and the making of policy decisions over a wide range of economic activities. The work throws light on the problems and conflicts involved in establishing policy goals.

EDWIN A. ANDERSON

*Board of Governors of the
Federal Reserve System*

Saving in India. New Delhi: National Council of Applied Economic Research, 1961. Pp. xii, 188. \$3.00.

This monograph is a valuable contribution to the research on recent economic development in India. Its primary purpose is "to arrive at the best possible estimates of saving that originate in different sectors of the economy, identify the components of saving for each sector and investigate the pattern of their utilization." The economy is divided in three major sectors: individuals' saving, corporate saving, and government saving. The Council's estimates of aggregate saving are the most comprehensive of all available but as mentioned in the study they are "still subject to a number of significant deficiencies."

The study covers the period 1948/49 to 1957/58 but lack of information for the early years necessitated interpolation of data. In the last year reviewed the total net national saving based on direct estimates amounted to U.S. \$2,250 million. The amount for the five years 1953/54 to 1957/58 totaled U.S. \$9,586 million in 1952/53 prices. Of this amount individual saving represented 82.2 per cent, government saving 13.6 per cent, and corporate saving 3.5 per cent. Thus more than four fifths of saving originated in the individuals' sector while the proportion of the corporate sector was surprisingly small. The individuals' sector comprises all types of households, farms and non-farm unincorporated enterprises engaged in manufacturing and other business enterprises. The savings in the sector are both personal and business savings.

It is obvious that the monograph suffers from lack of data in many fields. Considering that perhaps more than one-third of the Indian economy is nonmonetized, any estimate at this stage cannot but be very approximate. This applies particularly to saving in physical assets which accounted for about 60 per cent of the individuals' sector saving.

It was easier to collect information on saving in financial assets especially on savings accumulated at financial institutions including provident and pension funds and life insurance. Annual savings at financial institutions increased from U.S. \$152 million in 1948/49 to about U.S. \$500 million in 1957/58, of which contractual savings represented more than two-fifths. The largest single source of savings is now funds accumulated at provident funds.

The study does not deal with the problem of freely transferable savings which are very important for the flexibility of the national economy. In the estimate of this reviewer not more than one-third of the total increase in savings at financial institutions can be considered fully transferable. All the rest is reserved for use in the public sector.

Great ingenuity was displayed in getting estimates of non-financial saving in the individuals' sector. Among the many practical limitations the lack of statistical information separating business from personal accounts should be mentioned. Useful estimates could be obtained only for building construction, noncorporate business assets, farm investment, and some items of transport equipment. Many components of this large sector had to be omitted. It can be assumed that various gaps will be filled once the urban and rural saving surveys now being prepared by the National Council are completed. In spite of statistical and other limitations some of the features of saving in the sector are worth mentioning. Investment in rural and particularly in urban construction accounted for more than 60 per cent of the individuals' sector saving. The estimates on this type of investment are based largely on data on consumption of cement and steel.

The position is much better with regard to information on saving in the government and corporate sector. The government sector is divided into the administrative departments and the commercial enterprises. Net saving in this sector was obtained from a surplus in commercial enterprises. Contrary to the planners' expectations hardly any surplus on revenue accounts emerged. The estimate of saving in the corporate sector is based on a combined balance sheet covering the core of the sector. Net savings in this sector were small throughout the period and very small in the nonfinancial corporate sector. On the average the percentage of retained earnings of profits after taxes was only about 30 per cent and thus only a small proportion of new net investment could be financed from this source. This sector supplied only about 3 per cent of net national saving which is less than its share of the national income.

The study concludes that the national saving-income ratio rose from about 6 per cent in the period 1948/49 to 1950/51 to 7-8 per cent during the five years of the first five-year plan, and to 9-10 per cent during the first two years of the second plan. The higher figures were derived from the national accounts' indirect estimate of total saving. These figures fit rather well into the assumptions of the five-year plans. The authors estimate also the propensity to save though well aware that these estimates are conjectural for a number of reasons. They arrive at a figure of at least 20 per cent, which was the target of the second plan. This reviewer believes this figure to be too high and requiring additional scrutiny. It should be noted that gross saving in the individuals' sector was substantially higher than its gross investment so that this sector provided a surplus available for financing of investment in the other sectors.

It may be hoped that the National Council, which has started its work so well, will be able to expand the statistical coverage, to improve on the methods used, and to produce estimates somewhat less exposed to a wide margin of error. Yet despite all difficulties the study has achieved its primary objective and supplies a kind of rough x-ray of the pattern of saving and investment in India which can be helpful to the planners in India and elsewhere. The findings provide good evidence that even in countries with a very

low per capita income saving and consequently investment can be stepped up to a large extent and within a rather short period of time.

ANTONIN BASCH

University of Michigan

Social and Economic Frontiers in Latin America. By HARRY STARK. Dubuque, Iowa: Wm. C. Brown Co., 1961. Pp. xx, 421. \$7.25.

This book is rather hard to classify. It is written in a popular, even colloquial, style, designed to appeal to the general reader, and it has chapters on political-military organization in Latin America, Communism, and Anti-Yankeeism in Latin America; also a "case study" of Cuba. There is coverage of the main sectors of the economy (of which the balance-of-payments section is one of the best). There are 53 figures (maps and graphs) and 39 statistical tables, which bring together much useful reference material. With the exception of a few chapters, however, the topics are treated at a rather elementary level.

The preface suggests that the book is designed as a textbook for "courses in Latin American subjects." The economic analysis is not sufficiently sharply focused, however, to recommend this book for students with a sophisticated economic background.

GEORGE WYTHE

Washington, D.C.

La distribución del ingreso y el desarrollo económico de México. By IFIGENIA M. DE NAVARRETE. Mexico, D.F.: Instituto Mexicano de Investigaciones Economicas, 1960. Pp. 99. 20 pesos.

The widening scope of economic-development efforts and the importance recently given to investment in human capital, and in particular to social projects and reforms in Latin America, make books of this kind extremely valuable.

It is commendable that despite the scanty and dispersed statistics available (there are no regular national income figures prepared in Mexico), someone should attempt to analyze Mexico's income distribution in relation to its economic development; and what is more, should be willing to tackle the job single-handed. Despite a painstaking job, the book falls short of the mark in this reviewer's opinion. This is primarily due to the overwhelming odds involved in throwing light on the effects of the unequal income distribution on the economic development of Mexico.

The book consists of two parts—one is theoretical, while the second focuses on the distribution of the product by industrial origin, distributive shares, and income levels. The two parts are only loosely related to each other.

The theoretical analysis leads the author to argue that the slope of the consumption function is rather steep in spite of the inequality of income distribution, while it generates heavy imports of luxury goods. Both factors work towards a low savings ratio out of disposable income and a high propensity to import. Therefore, she argues, if the concentration of income promotes a demand for imported consumer goods rather than larger savings, a more egalitarian income distribution is a necessary condition for economic

development, i.e., it would increase the demand for domestic-made products without changes in the level of savings. The demand-pull would be an additional incentive for investment and growth.

The low savings ratio is later geared to the Harrod-Domar model in an attempt to show its depressive effect upon the growth rate. All in all, this section is faulty on several grounds and inconsistent with the available data. As could be expected, later samples have shown that the savings ratio goes up from lower to upper incomes and the import of consumption goods of all kinds accounts for a minor percentage—18 per cent—of Mexican imports. Besides, the Harrod-Domar, single-commodity, fixed-coefficients model, whatever its merits on other grounds, has considerable shortcomings when used as the basis for a theory of income distribution, which the author does not take into account. My own feeling is that the theoretical part of the book is irrelevant for the professional economists and would be confusing to the undergraduate.

The second part is a collection of data with regard to which the author carefully cautions the reader as to the dubious nature of the available statistics; e.g., profits account for 41 per cent of national income in 1950 according to one estimate and 26.7 per cent according to another. Its main findings are an increase of industrial and agricultural output and productivity, and a shifting trend from agricultural employment into industries and services. An increment is noticeable in the average income of farmers, but farm laborers were relatively worse off in 1950 than in 1940, although their number decreased from 35 to 20 per cent of the labor force. The disparity between the average incomes of entrepreneurs and independent workers and those of employees both in the agricultural and nonagricultural sectors grew larger, particularly in the case of the latter. While 20 per cent of the population in the lower-income strata deteriorated economically in relative and absolute terms from 1950 to 1957, 30 per cent of the population in that period deteriorated in relative terms, improving slightly in absolute terms. Thus the upper half improved in absolute as well as in relative terms being better off than they ever were before.

In the section that deals with the national distribution of income, which seems to me to be the best chapter of the book, cross-section samples of the Statistics Department are used. Here it is shown that Mexico City and the northern Pacific coast area with 20 per cent of the population have an income 1.8 times larger than the nation's average. The central plateau and the southern part of the country have an average income close to two-thirds the average for the nation. It would be worth while to further analyze the extent to which the country is siphoning resources to its richer regions in the way Myrdal described.

Finally, although this is a thought-provoking book, it raises more questions than it is possible to answer, given the present development of Mexican statistics; and while the author offers well-grounded opinions, she mingles these with value judgments, giving the impression that she has not delved into the subject deeply enough.

LEOPOLDO SOLIS

Mexico City

The Philippines: Public Policy and National Economic Development. By F. H. GOLAY. Ithaca: Cornell University Press, 1961. Pp. xv, 455. \$6.75.

This volume is the outgrowth of Dr. Golay's year of field research in the Philippines during 1955-56 under a Fulbright scholarship, as well as a Cornell Southeast Asia Program travel grant.

According to the foreword, the study "is an attempt to examine the role of public policy in postwar Philippine *national* economic development." Following an introduction that includes a brief survey of postwar economic developments in the Philippines, the analysis is organized on the basis of various facets of public policy, viz., exchange rate policy, commercial policy, industrialization policy, economic planning, etc.

While recognizing that postwar economic growth in the Philippines has been rapid, Golay is nevertheless severely critical of many Philippine economic policies under which that growth has occurred. "The Philippine Congress blithely enacts consumer price controls, personal income taxes, and land reform legislation which it has no intention of seeing enforced. Similarly, there have been a succession of more-or-less comprehensive economic plans for accelerated economic growth which have largely been ignored by the policy makers" (p. 408). Further, Golay laments the harshness of the emerging Philippine economic organization. "Income and wealth are concentrated, political power is closely correlated with wealth, and welfare goals are assigned low priority" (p. 408).

Golay guardedly forecasts continued economic growth in the Philippines. He observes that: "The unity of the political elites has been permanently destroyed" (p. 415); Philippine society is becoming increasingly sophisticated (college students account for a higher proportion of the population in the Philippines than in any other of the less developed countries); a middle class is emerging as a result of increased internal migration, urbanization, and economic growth; specialized economic institutions, such as common stock mutual funds, life insurance, social security, postal savings, rural banks, and rural credit cooperatives, nurture economic growth; foreign savings, particularly those supplied by the United States, will continue to assist in promoting economic development; Philippine commercial policy is becoming increasingly "normalized," i.e., monopoly windfalls arising out of import restrictions are increasingly being diverted to the government; and the Philippine economy gives promise of remaining stable, in part due to the diminished importance of foreign trade.

The principal factors that will limit Philippine growth, Golay feels, stem from the unnecessarily low levels of foreign exchange earnings; the rapid rate of population growth (about 3 per cent annually); the unlikelihood that industrialization will expand sufficiently to keep pace with the annual addition to the labor force; and the low marginal propensity of Filipino society to save.

Golay discusses two other factors that bear on Philippine economic growth: the conspicuous concentration of wealth and the role of the Roman Catholic Church. He takes issue with those who feel that the concentration of wealth augurs well for promoting economic development; he observes that the Philip-

pine Congress shows no willingness to employ either wealth or agricultural income as a significant tax base, and that the landed gentry are strongly disinclined to shift from their tradition-bound role of rent receivers into entrepreneurs or dividend receivers. Golay feels that the concentration of wealth is likely to be a neutral factor in the economic development of the Philippines. The Catholic Church, he observes, has no "single unified church policy with regard to the more earthy details of political, social, and economic life" (p. 422). He feels that the elements of the church that are identified with the *status quo* will obstruct material progress, whereas other elements—notably the Jesuit order—"represent a potent force for evolutionary change" (p. 422). On balance, Golay is of the opinion that the church will play only a passive role in Philippine economic development.

Golay also calls attention to serious social problems that tend to resist alleviation through economic growth, such as the concentration of wealth and the substantial failure of the rural and urban proletariat to benefit from economic development. He feels that to deal with such problems, "Land reform, preferably with a substantial element of expropriation, is warranted on grounds of equity" (p. 423), and that the Philippine fiscal system needs overhauling. He believes also that the Philippines should (but probably will not) provide for the social and economic assimilation of aliens, notably the Chinese, in a manner that will subordinate emotion to reason.

Golay concludes that "changes favorable to further economic growth . . . should be assessed as favorable" (p. 426) but "The ultimate outcome of Philippine development is not particularly promising as population growth will ultimately press upon available resources" (p. 427).

The book is to be recommended primarily to those who are already familiar with basic Philippine problems but wish to have an up-to-date appraisal by a competent field researcher. With most of Golay's views, few objective analysts, particularly in the United States, will quarrel. Perhaps, however, he has attached too much importance to fiscal matters, particularly the exchange rate problem.

Golay has surveyed many facets of the Philippine scene and has assembled a great deal of information. Not the least of his contributions is an excellent "Bibliographic Essay." His book is not easy reading, however, largely because of excessive detail, much repetition (only partly due to the functional organization of the material), and too much statistical data interspersed in the text.

BEN DORFMAN

Washington, D.C.

SSSR-S.Sh.A. (*Tsifry i fakty*). (USSR-U.S. Figures and Facts.) By A. G. AGANBEGUAN, T. A. ARTAMONOV, YA. A. IOFFE and YU. M. SHEYNIN. Moscow: State Publishing House for Political Literature, 1961. Pp. 133.

The book under review consists of six parts: (1) general information; (2) basic stages of the economic contest; (3) industrial production; (4) agricultural production; (5) standards of workers; and (6) education and science. It is devoted to a popular theme in the Soviet Union, concerning economic competition between the USSR and the United States.

In this book there are many inaccuracies and distortions. For example, the tempo of increase in industrial production in the USSR is exaggerated, and for the United States it is underestimated. Actually, productivity of labor in agriculture in the USSR is more than three times lower than in the United States. The statement that the USSR has outstripped the United States in 1957 in production of animal fats and in 1959 in the production of milk does not correspond to the facts. Average per capita living space in the United States is more than twice that in the USSR. Many other misinterpretations and errors are found in the book.

The major theme of the book may be condensed into one statement: By 1970, and maybe earlier, the USSR will outstrip the U.S. in per capita production and in the level of real income (pp. 26, 89).

This statement has to be approached separately from the point of view of the Soviet consumer and the Soviet military potential. In the reviewer's opinion, the Soviet Union will never be able to provide its citizens with a standard of living comparable to that in the United States. One of the most important reasons for this is that the criteria in the two countries are completely different. Two illustrations will suffice. In the United States nearly every family today has either a private home or a separate apartment. The Soviet government has promised every family a small state-owned apartment with an average of 86 square feet of living space per person by the end of 1965. Although this means, at best, two persons per room, it is only a promise, and there is overwhelming evidence that this plan will not be fulfilled.

It is well known that an automobile is an important part of the U.S. living standard; in fact, almost every family in the United States has at least one car. The Soviet government has promised its citizens public transportation in sufficient quantity in 20 years, albeit free of charge. In fact, the same picture may be seen in other branches of Soviet public service. It is extremely significant that, 43 years after the revolution, the Soviet worker still spends 75 per cent of his income on food and consumer goods, as compared to 37 per cent in the United States (p. 93).

But there are other aspects of the competition between the two countries in which the balance is not nearly as favorable for the United States. Measured in GNP, or industrial production, the Soviet growth rate is twice that of the United States, although the effect of this on the Soviet citizen is negligible. Because of the military significance of certain types of production, the Soviet government undoubtedly can expect the fulfillment, and in some cases the overfulfillment, of their production plans for steel, petroleum, gas, electric power, cement, machine tools, etc. Often, the excessive emphasis that is placed on how far the Soviet Union is behind the United States in the production of cars, washing machines, refrigerators, tends to carry over to an underestimate of the Soviet military capability. This completely ignores the basically military nature of the Soviet economic system.

Now, after the establishment of control commissions with extraordinary powers to deal with false economic reporting by managers in agriculture and industry, underestimation of Soviet production becomes even more likely. Indeed, the fact of the degradation and punishment of hundreds of persons last

year for deliberately distorting and falsifying statistical data, gives the analyst the false impression that all Soviet published statistics are false. This is not the case, because Soviet statistical data are, generally speaking, trustworthy; frequently, however, their interpretation is either unscholarly or tendentious.

The book under review contains much statistical data on many branches of the Soviet economy and should be of interest to all specialists on the Soviet Union. The reader who is not familiar with Soviet statistical practices, however, should be wary of much of the data and careful in drawing his conclusions.

T. SOSNOVY

The Library of Congress

Le plan septennal soviétique: études et documents. Cahiers de l'Institut de Science Économique Appliquée, No. 107 (supplément), Série G, no. 10. Paris: I.S.E.A., 1960. Pp. 367.

Recently a delegation of French economists visited the State Planning Committee of the Soviet Union and, after some begging, the Russians presented the French with a valuable souvenir: a complete set of blank forms of the current seven-year plan of the USSR (1959-1965) as well as the official instructions on how to fill them out. These documents appear in translation in the *Cahiers* under review. Though empty of statistics, the forms and instructions furnish a comprehensive and dependable view of the current methodology of Soviet economic planning.

Some features strike the reader at once. For example, almost the whole plan is drawn in kind, not in money. Out of more than 200 tables, the two or three drawn in value terms are the ultimate over-all balance sheets, superimposed upon the skeleton of physical and technical targets. It is hardly plausible that a truly economic optimum can exist in such a structure. Moreover, there is no evidence in the instructions that anyone even thought to take such an optimum into consideration.

Another noteworthy feature of the seven-year plan is the fact that defense expenditures and output as well as such projects as the rockets to the moon are not part of it. This means that, as before, the planning of defense economics is separated from the national economic plans and is not under the Gosplan's jurisdiction. This separation is an important factor that contributes to the disproportionate development of selected sectors of the Soviet economy.

The French collection of the seven-year plan documents is accompanied by two explanatory articles. Basile Kerblay has written a general survey of Soviet planning methods and has compared the present collection of forms with a similar one which the Russians published in 1936. It must be mentioned here that another official collection of similar forms and instructions was also published in 1937 and is available at least in the library of Columbia University. A systematic comparative study of these planning documents may yield an interesting dissertation.

Héni Chamber has contributed a revealing discussion of Soviet regional and local planning within the framework of the seven-year plan. Some basic forms of this type of planning are included in the present collection. This is

a novel subject not only for Western students of Soviet economics but also for the Soviet planners themselves.

Our libraries must acquire this issue of the *Cahiers* for their Soviet collections.

VSEVOLOD HOLUBNYCHY

Columbia University

Economic Development, Analysis and Case Studies. By ADAMANTIOS PEPELASSIS, LEON MEARS and IRMA ADELMAN. New York: Harper & Brothers, 1961. Pp. viii, 620. \$8.50.

The title of this book leads one to expect more than is found. It is no doubt a good idea to provide a number of cases studies and analysis for an avowedly undergraduate textbook in economic development, but the lack of a strong organizing principle, a theoretical structure or, at the least, greater unity is a serious defect in this attempt. The authors, it is true, state that a loose-structured book was their intention. Moreover, the authors have planned two books: one, an undergraduate text which is the work under review, and a second, a theoretical book for graduate students to be published later. This first book is made up of two discrete elements: Part I, 6 chapters on "the key determinants of economic development," i.e., natural resources, human resources, capital accumulation, technology, entrepreneurship and socio-cultural factors; Part II, 12 case studies written by two of the principal authors and ten other people. Of the chapters in Part I, Pepelasis wrote two-thirds with Mears writing the chapters on human resources and sociological factors. The third author, Mrs. Adelman, seems to have done the editing, though originally she was supposed to have written a theoretical section, which idea was dropped in favor of the second book still to come.

While this absence of theoretical structure in an undergraduate textbook may be acceptable to some economists, this reviewer feels that the typical upper-division text in this field should have more body and unity. Certainly texts currently in use, like those of Lewis and Higgins, give the student much more structure to take home. In the usual course, such case studies are typically contributed by student papers obviously with much less expertise than in these 400 pages, but having the merit of requiring the students' digging out of data themselves. To a certain extent, students should benefit from a demonstration effect, but this seems hardly to balance the loss of vital material of a systematic nature. At the very least some of these case studies could have been dropped to have made way for materials of higher marginal utility. This lack of balance, which could have been remedied with relative ease, seems to be a critical central defect of the book.

Thus the classical theory of economic development, the Marxist model, Schumpeter, Hansen and others are all conspicuous either in total absence or with some minor reference to a part of their theories. The celebrated Harrod-Domar model is not found in Part I nor cited in the author or subject index. Moreover the whole area of policy—"what to do" questions, so dear to the heart of the undergraduate, particularly if he is from an underdeveloped country—receives no independent identity, only implicit treatment in the

"determinants" chapters or mention in some case studies. For example, foreign aid is barely touched on in the capital chapter.

The second major criticism is an unevenness of treatment which pervades the book. Not only does the work suffer from the unevenness of content and style which is the *bête noire* of most multi-authored works, but within the chapters, there is uneven allocation of space to technicalities at the expense of larger issues. Thus investment criteria receive 9 pages of imbricated materials from technical articles while the issue of "big push versus unbalanced growth" receives only 3 pages before it gets mixed up with "planning versus free-markets" (not separately captioned). This unevenness is intensified in the case studies where each author seems to have written any way he pleases because, according to the five-page introduction to the case studies, students "will be compensated for the inevitable loss in unity by being confronted with a more realistic picture of the diversity of situations faced by countries attempting development." Perhaps so; but this reviewer suspects that the student will simply be confused by the sprawling scene.

The third critical weakness in the book is the lack of analysis as applied to the case studies. Little or no forward or backward linkage is used to relate the two parts of the book which stand in splendid isolation. It would seem that the authors at least could have devised some criteria of what to include and in what order, so that the reader could make cross-comparisons. It is true that the case studies themselves appear to have been done with some competence, but much of their materials appear dated. Mexico's indexes come up only thorough 1956. The India study includes virtually no indexes and its discussion comes up through the middle of the second plan with nothing on third-plan horizons. The great modern underpinning of India's third-plan investment by consortium foreign aid is totally missed. Perhaps such stale data is unavoidable in a composite work with inevitable publishing lags, but it detracts very much from a work where the case studies are not buttressed by more analysis.

On the positive side, there are included some hard-to-find, unusual cases like Uganda, Belgian Congo, Yugoslavia and New Zealand (the latter by the distinguished scholar, J. B. Condliffe) and the bibliographies are helpful. All in all, in spite of the above weakness, the book is a useful addition to the literature in the economic development field.

DANIEL L. SPENCER

Howard University

Economic Systems; Planning and Reform; Cooperation

Das sowjetische Wirtschaftssystem und Karl Marx. By GÜNTHER WAGENLEHNER. Cologne-Berlin: Kiepenheuer & Witsch, 1960. Pp. 354. DM 15.80.

The stated purpose of this book is to compare Soviet economic theory and practice, as depicted in the USSR Academy of Sciences' undergraduate textbook, *Political Economy*, with Karl Marx's *Capital* and thus establish "to what extent Soviet socialism differs from Marx's capitalism." By taking an extremely superficial view of both, the writer has arrived at the conclusion

that such a difference does not exist. Were it not for this unfathomed attitude, the book might have been of great interest. We lack as yet a thorough, scientific account of the relationship between Marxian and Soviet economics, even though we all seem to agree that such a relationship exists and that it is in many ways decisive.

Wagenlehner's message is scarcely different from what is habitually written in popular propaganda monthlies on this subject. Without quoting *Capital* in any way to substantiate his contentions, the author argues that the designers of the Soviet economic system not only learned their economics from *Capital*, but have also applied *Capital* in Soviet practice. While there undoubtedly is a grain of truth in this observation, the book would have contributed more if it had explained why Soviet economists maintain that some elements in their system are capitalistic "only in form, rather than in essence."

Wagenlehner lays his heaviest stress upon his discovery that Soviet economic theory admits that total product in the USSR can be broken down into Marx's $c + v + s$ categories. He thinks that the presence of s —that is, surplus product or surplus value—is especially revealing of something implicitly hideous, and that it proves beyond any doubt that the exploitation of labor is widely practiced in the USSR. He obviously disregards the fact that, to Marx, the existence of s was a normal thing and a necessity under all socio-economic systems, and that it alone and by itself cannot be adduced as proof of exploitation. Although it is true that Marx the politician and moralist occasionally condemned all of s as such, and sometimes indiscriminately called exploitation even the cases when the rate of s increased as a result of the introduction of new technology, Marx the economist always cherished his own proposition that s was prerequisite to all progress and accordingly saw true exploitation not in the production of s , but in its distribution; and that, specifically, only in that portion of s which was not reinvested to increase employment, production, and tangible wealth of society as a whole, but was wasted instead on unproductive, luxurious consumption of the rich.

It may, indeed, be interesting to establish whether or not labor exploitation in the Marxian sense exists in the USSR. But Wagenlehner's book has not proven its existence. To prove his hypothesis, it would be necessary (a) to study the relative incomes of the different classes of the Soviet population in different territories per unit of equal time worked (complex and skilled labor reduced to simple labor by some formula with the costs of training as weights); (b) compare the income differentials with similar relative income distributions under capitalism, if only to check for trends; and (c) to analyze the actual end-uses of s in the national income and compare them with Marx's dictum that, under his socialism, s was supposed to be used to reduce the income differentials and to augment the working people's living standards at least as fast as the rate of growth of their labor productivity. Presently, it is mainly the fact that the Soviet government conceals the income statistics of its population that provides ground for Wagenlehner's hypothesis to be held by many.

Money, Credit and Banking; Monetary Policy; Consumer Finance; Mortgage Credit

Interesse, moneta e credito. By BRUNO JOSSA. Pubblicazioni della Facoltà Giuridica dell'Università di Napoli, No. 46. Naples: Editrice Jovene, 1960. Pp. xii, 343. L. 3,500.

This essay, by a young economist of the University of Naples, is, in my view, a valuable work of criticism and exposition, contributing several significant original ideas (or at least ideas never so clearly formulated), but marred—again, in my view—by several rather curious errors. It is certainly worthy of careful study by students of monetary and interest theory.

Jossa's approach to the problem of interest theory is perhaps less ambitious than that of Conard,¹ but it has essentially similar aims, and reaches in some respects similar results. Jossa is less interested than Conard in following up every aspect of the subject; instead he concentrates attention on particular aspects that most concern him, with only casual and therefore sometimes inadequate treatment of other aspects of interest theory. His purposes are to bridge two gaps in interest theory: first, the gap between the "real" theories of interest (long run, flexible wages and prices, full employment) and the monetary theories (short run, rigid wages and prices, variable real income), and in the process to criticize both and reformulate them into a more general analysis; and second, the gap between interest theory and banking theory. He makes useful contributions in both respects.

In a brief review it is impossible to comment on more than a few points, and there are many that are worthy of comment, both commendatory and critical, in a work so closely reasoned, and which ranges so widely over a vast and controversial literature. After a short introduction summarizing the present state of interest theory, the author builds systematically a "real" theory, for an economy with perfectly flexible wages and prices, without loans and without banks; he then introduces money (rained from heaven) and credit (loans); next, he assumes rigid wages and variable real output. What seems to me his more useful and original contribution comes (in Chapter 7) when he then introduces the commercial banking system, which—rather than heaven—supplies much of our money, and assesses the banks' role in interest determination, both with flexible and rigid wages. The work closes with two chapters which criticize, in the light of his previous analysis, classical "real" theories and the monetary theories (in both liquidity-preference and loanable-funds forms) as these have been expounded by numerous authors. An appendix deals with efforts to reconcile loanable-funds and liquidity-preference theories.

The first major defect, in my view, is the way in which Jossa introduces the demand for money in his system. It exists, he first suggests, because of uncertainty regarding the sequence and timing of inpayments and outpayments, thus failing to recognize that, even with certainty, the very use of money as a medium of payments requires the holding of transactions balances. His

¹ J. W. Conard, *Introduction to the Theory of Interest*, Berkeley, University of California Press, 1959.

initial demand for money (which he properly suggests is interest-elastic) is, in my view, to be called a precautionary demand, although he later seems to identify it as a transactions demand. Rather casually, he subsequently introduces what he calls a "precautionary and speculative demand," but fails, I think, to see or at least to expound the real heart of the Keynesian contribution as being a speculative demand for money associated with the existence of a loan market and a stock of bonds. Thus he repeatedly asserts (at least until the banks are introduced) that the existence of bonds makes little difference. For Keynes, and in my judgment correctly, the very existence of a bond market makes all the difference, because it provides a new kind of wealth-holding medium which differs from money in having a yield, and from capital goods in that its (money) yield is certain. The peculiar market characteristics of this third form introduce a systematically disturbing element (attempted hoarding and dishoarding through attempted conversions of bonds for cash and vice versa) which prevents the market rate of interest from doing its job of stabilizing aggregate demand from consumption and investment spending. Jossa does not, in his later treatment, ignore speculation; but I feel that he fails to present its true significance in the Keynesian scheme.

In the course of his treatment of the Keynesian system, Jossa attempts to expand the famous Hicksian apparatus of SI and LM curves by adding a third curve, TT ("T" for *titoli di credito*—i.e., bonds). I will not go into my problems with this device, because the issues are complex and because I am not sure whether I want to say that the new curve is superfluous, formally wrong, or merely highly confusing.

The theoretical substance of the problem centers, however, on Jossa's treatment of the demand for money. Jossa wants to say that a change in the demand for money (including a movement along a schedule) can be at the expense or benefit of the demand for consumer goods, the demand for capital goods, or the demand for bonds, with different results in each case. The traditional Keynesian treatment prefers to say that if an increased demand for money is at the expense of the demand for consumer goods, two things have happened—an upward shift in the demand for money and a downward shift in the consumption function. It is certainly true that these two things can happen together, but there is no necessary reason why they should. At a given level of income one can well become more apprehensive about bond prices and wish to become more liquid, without any change in one's demand for consumer goods. Vice versa, one can decide to save more without changing his demand for money. (However, see third paragraph below.)

One can certainly think of capital goods (or inventories) as an alternative to money as a form of wealth-holding. An increased demand for money might, therefore, accompany a decreased demand for inventories or capital goods. For example, suppose that entrepreneurs expect falling goods prices. They may then wish to hold smaller inventories. But why should they wish to hold more barren *money* (Keynesian theory suggests) unless they also expect bond prices to fall (interest rates to rise)? Thus the traditional Keynesian treatment prefers to recognize that, although the investment function and the demand for money function can (and sometimes do) shift together, this should

be treated as two changes rather than one. If we follow this treatment, then it is not only formally correct but perhaps more illuminating to identify, as Keynes did, the demand for money as the reverse of the demand for bonds, in effect treating this pair of variables as one.

What Keynesian theory as usually expounded fails to do, however, is to recognize that it is not just the stock of money, but also the stock of bonds which is relevant, for the sum of these, plus equity in capital goods, is the total wealth of the community. Thus, it does make a difference, as Jossa so clearly emphasizes, whether new money enters the system in exchange for bonds (as through the activities of the central or the commercial banks), as rain from heaven (that convenient expository device), or through government financing of a current deficit.

Further, there is the important point, whose significance Jossa sees and builds into his system, that the demand for money may well be a function, *ceteris paribus*, of the amount of saving. This is not a new point (I recall it first in an article of Arthur Smithies more than twenty years ago, and it has reappeared in various guises since), but it is a good point and needs to be built into the theory.

Armed with this apparatus, Jossa usefully builds the commercial banking system into his macroeconomic models, and shows what follows from this. He tends, perhaps, to overstress the difference this makes for prediction of the effect of various parameter shifts; but this can be forgiven when illustrious forebearers have invariably done the same.

I think that I would argue that most of Jossa's insights are more relevant in a growth context than in the stationary equilibrium which seems most to concern him. With growth, and not necessarily *proportional* growth, of the various relevant stocks (capital goods, bonds, equities, money, total wealth), the effects which Jossa stresses assume particular relevance, and it is in this context that these problems have so far received particular treatment. Likewise, in the growth context, Gurley and Shaw, whose work Jossa does not review, have attempted to incorporate not only the commercial banks but also other financial intermediaries into the system, suggesting some illuminating hypotheses.

There is much more to criticize and to commend in this useful work (including much extremely rigorous criticism of previous work), but space permits me only to repeat that I believe this essay will greatly repay careful study.

The usefulness of the study would be much increased by an index, at least of names of authors cited.

GARDNER ACKLEY

University of Michigan

The American Financial System: Markets and Institutions. By JAMES B. LUDTKE. Boston: Allyn and Bacon, 1961. Pp. xii, 685. \$7.75.

In the preface to his book James B. Ludtke states that the "book is an outgrowth of considerable experience in the development of a financial institutions course, and it is designed to serve as a text in money and banking courses as

well as in financial institutions courses." The book is a massive (685 pages) tome, well written, with evidences of considerable recourse to technical literature instead of mere rehashing of other texts, and thorough treatment of all the institutional aspects of the U.S. financial system. Thus, I believe that Ludtke has succeeded in writing an excellent text that should compete successfully in the market for texts in courses on financial institutions. However, the predominantly descriptive nature of the work, with virtually no treatment of monetary theory or the theory of income determination, and only slightly greater attention to issues of monetary and fiscal policy both past and present, make me unwilling to agree to Ludtke's claim that he has written a text for courses in money and banking. Most of the texts in that field are not the answer to a teacher's prayer, and do not describe the U.S. financial system as exhaustively as this text, but they are far better balanced in their coverage. A teacher who wishes to stress theoretical aspects will find texts of the type of Chandler or Day and Beza much more to his liking. One who believes in giving his students a thorough grounding in the institutional framework of the U.S. financial system can do this with a text like Steiner, Shapiro, and Solomon, without having to sacrifice the theoretical and policy aspects of the subject.

The American Financial System uses the flow-of-funds approach as the key to its organization. After a brief introductory chapter, it deals very briefly with various types of national economic accounts and gives an interesting comparison of the flow-of-funds approach and other major approaches. The next three chapters deal with monetary standards, currency, and demand deposits, and cover in about 50 pages the range of material (money, commercial banking, banking history, etc.) which generally constitute a significant portion of other texts in the field.

The next 17 chapters (about 460 pages or almost 70 per cent of the book) cover four major sectors in flow-of-funds accounts: consumer and nonprofit organization sector, nonfinancial business sectors, government sectors, and rest-of-the-world sector, and the financial markets in which they interact. These chapters are well done and serve as an admirable introduction to the various financial institutions and instruments.

There is no separate section dealing specifically with the commercial banking and monetary authorities sector and the nonbank financial sectors of the flow-of-funds accounts. Instead, the discussion of these institutions is found in the chapters dealing with currency and demand deposits or in chapters dealing with the other four sectors.

The last section deals with national economic objectives and monetary and debt management measures. I found the chapter on objectives and the section dealing with techniques of debt management particularly praiseworthy and more informative than comparable treatments in other texts. The treatment is generally descriptive rather than prescriptive. When policy conclusions are advanced, they usually reflect the position taken by the Federal Reserve Board, e.g., no controls are now needed over financial intermediaries.

The analytical rationale behind the flow-of-funds accounts is clearly stated in the Federal Reserve's discussion of the accounts. "Developments and de-

cisions in the financial sphere of the economy and developments and decisions with respect to income, production, and the markets for goods and services are interdependent and mutually determining. Liquidity position, portfolio composition, credit availability, and changes in each are reflected in markets for goods and services and thereby in the changing total and composition of spending and output; at the same time, changes in income, prices, expenditures, and output influence savings and investment decisions, borrowing and liquidity needs, and thus flows through financial channels."¹

The interaction of monetary and real phenomena within the same system of accounts and the relatively greater degree of disaggregation than is usually found in national income accounts should make the flow-of-funds a powerful analytical tool. Unfortunately, the author has not exploited its possibilities.

There are some minor criticisms of specific points. In the discussion of relative yields on bonds and common stocks, the author talks as if dividends were the major determinant of the level of common stock prices. He states, for example, "In some instances, the *dividend income* would have to increase at a phenomenal rate to justify the high market price of some stocks" (p. 582, emphasis added). Investors are now generally looking at total profits and their trend, rather than merely at that part of profits which happens to be disbursed as dividends. In the otherwise excellent discussion of national economic objectives, the omission of the problem of balance-of-payments equilibrium is not permissible at the present stage of U.S. economic history.

In his discussion of saving and investment, the author accepts the flow-of-funds definitions which, by including purchases of consumer durable goods in both gross savings and investment, make the consumer and nonprofit sector appear as the predominant supplier of saving and contributor to investment. The apparent contradiction between this and the generally held notion that the business sector accounts for the major share of gross saving and investment is not pointed out or explained. I suppose I am showing my puritanical streak, but I find it difficult to accept the idea that purchases of consumer durables constitute savings and investment, despite the fact that they give off a stream of services over a long period of time. The connection between investment and economic growth is made very tenuous by lumping business investment and purchases of consumer durables under investment.

Public Finance; Fiscal Policy

Fiscal Theory and Political Economy: Selected Essays. By JAMES M. BUCHANAN. Chapel Hill: University of North Carolina Press, 1960. Pp. 197. \$5.00.

This is a useful and welcome set of essays. They "... represent various efforts, made over a ten-year period, to note some of the limitations in orthodox thinking on fiscal theory, to raise what appear to be some of the relevant

questions, and to explore some of the challenging issues that arise in this field of study" (pp. 3-4). Buchanan's interest has been drawn especially to the area of methodology, and these essays exhibit it clearly. Their range is wide, although they hang together in their common concern with an attempt to specify a general framework for fiscal analysis. They fall into three categories.

The first two essays are concerned with the pure theory of government finance. The first is so labeled, while the second, appearing in English for the first time substantially recast from its original Italian version, examines at some length the Italian literature on fiscal theory. The next three studies investigate "the process of collective choice under the individualistic assumptions about the state." They represent a critique of welfare economics in general and of recent contributions to the analysis of social choice in particular. Their titles suggest their content: "Social Choice, Democracy, and Free Markets," "Individual Choice in Voting and the Market," and "Positive Economics, Welfare Economics, and Political Economy." The last three papers deal with the methodology of tax analysis—incidence theory, the excess-burden argument, and the problem of equity in a system of federalism.

The thrust of Buchanan's argument is that traditional fiscal theory suffers from two serious defects: (1) Governmental fiscal activities are treated as if they were divorced from the decision-making activities of private groups, except as taxes may impinge on these decisions directly. (2) Even so limited, fiscal analysis has too often used particular-equilibrium tools of analysis, rather than taking the more relevant general-equilibrium approach. These criticisms may not seem startling at the present time. Examination of the expenditure side of the government fisc has been increasingly carried out in recent years, and the application of general-equilibrium analysis to fiscal theory has become much more common. Yet, this shift in emphasis is due, at least in part, to Buchanan's work. Since the points he makes are important ones, it is difficult to overemphasize them.

Of the eight essays, the three that appear for the first time can be most usefully commented on in this review. Buchanan's critical review of incidence theory is a model of careful and judicious appraisal of the debate between Rolph, Musgrave, Due, and others on excise and sales taxes. One can certainly agree with Buchanan's desire to separate tax incidence from the incidence of monetary policy—to treat it as a problem of relative pricing. One can also applaud his view that a tax must impose a real burden or be functionally useless. Yet, he accepts the proposition that a general excise tax falls on factor incomes in a fashion similar to an income tax and attributes it to Rolph and Brown. Rolph himself has stated very clearly that his analysis is based on *given* factor supplies and zero saving, and that when these assumptions are relaxed, factor incomes after tax may not be proportionately reduced by a general excise tax. Such a tax can then alter factor supplies and factor rewards in a way that *may* make the result substantially different from that of a general income tax. Buchanan's conclusion is too strong that "there seems to be widespread agreement that the Brown-Rolph conclusions concerning the incidence of a completely general excise tax are correct" (p. 139). Buchanan must have a number of empirical relationships in mind when he adds: "Journalists

and politicians need to learn that the difference between a general excise tax, or a whole set of partial excises, and a proportional income tax is slight indeed." This may be true of the fixed-factor case, but one should be careful not to base policy judgments on such a limited set of assumptions.

The essay entitled "Comparative Tax Analysis and Economic Methodology" deals with the excess-burden argument of indirect taxes. Buchanan's results generally agree with those of Rolph, Break, Little, and Friedman. But I had difficulty with the first part of the essay in which he attempts to establish the proposition that an excise tax of yield equal to that of an income tax will reduce the consumption (production) possibilities open to the private sector by more than the income tax. Since this conclusion rests on the usual simplifying assumptions, this excess burden is over and above the usual excess welfare burden. I was not convinced by his analysis, and cannot, in brief compass, disentangle my differences. He works with a production-possibility schedule under conditions of diminishing returns. If his is a general theorem, it should hold under conditions of constant returns, but does not. I suspect, therefore, he is throwing into the analysis the change in the marginal rate of substitution that results in the new excise-tax equilibrium. Moreover, he finds a difference in result when the government taxes its own purchases from that when they are exempt. This seems to me a dubious point of distinction on which analysis should turn, since the real tax yield from the private sector remains unchanged in both cases.

Finally, a word on the longest essay—that on the development of fiscal theory in Italian economics. This is an important exegesis of the Italian literature replete with references and a general bibliographical note at the end. Buchanan is favorably impressed by their approach, but also points up its weaknesses. In contrast with the Anglo-Saxon tradition they have framed fiscal theory in a more general economic model, recognizing its interdependence with the private sector. Problems of collective choice, almost wholly ignored in our tradition, have received much attention and discussion. But he also finds their tradition as lacking in a reforming spirit or guided by the desire for problem-solving.

This significant set of essays will find its way into the required reading lists of graduate courses in fiscal theory. Buchanan is a careful scholar who argues his position cogently. He has the imagination to be unorthodox, not for purposes of effect, but only when his examination of the orthodox view finds it inadequate to deal with the problem at hand. His position is marked out by careful and deep thought. Disagreement forces the reader to grapple with fundamental issues, and in the process he becomes a wiser man.

E. CARY BROWN

Massachusetts Institute of Technology

The Ideologies of Taxation. By LOUIS EISENSTEIN. New York: The Ronald Press Co., 1961. Pp. vii, 263. \$5.00.

This is an admirable little book from many points of view. The style is lively and the content is solid. The documentation is thorough and scholarly.

Eisenstein starts with the simple proposition that our people are divided

into economic interest groups and that each of these groups tries to pay as little in taxes as it can get away with, so to speak. In its effort to get away with a small share of the tax burden, each group develops an ideology of taxation by way of defending its position. The purpose of the ideology is not to state facts but to obtain action in the desired direction.

Eisenstein distinguishes three main ideologies of taxation: (1) "ability to pay," (2) "barriers and deterrents," and (3) "equity."

In the main, poor people (and intellectuals) propound the ideology of ability to pay and urge the use of steeply progressive personal and corporate income taxes. These people are very numerous and thus have some political influence.

Well-to-do people promote the ideology of barriers and deterrents, to the effect that progressive taxation of income will destroy both the willingness and the ability of wealthy people to save and invest, and thus the economy will topple down in ruins. These people are less numerous than the poor but their average per capita political influence is much higher. They get exceptions in the tax laws made in their favor. Prominent among such exceptions are the preferential treatment of capital gains, depletion allowances, income splitting, and accelerated depreciation.

Once such exceptions are made, the proponents of equity find other cases which are in some respect similar to the excepted cases and urge the expansion of the exceptions to cover these similar cases. The advocates of equity are pretty much the same people as those who promoted the exceptions in the first place.

Eisenstein demonstrates beyond any reasonable doubt that all of these groups of people disregard unpleasant facts and are woefully inconsistent; but, as he points out repeatedly, such disregard and inconsistency are not to be held against them too much. Their purpose is not to be factual and consistent but to be effective in getting action favorable to their position.

As noted above, most of the proponents of the ideology of barriers and deterrents, as Eisenstein has observed them, are of the feeling that the *critical* shortage in our economy is the shortage of willingness and ability to invest. There is the opposing point of view that our *critical* shortage is the shortage of good customers to buy what we are already capable of producing. We undertake to resolve this difference of opinion (or feeling) by political processes. The outcome is in some degree a compromise, but the friends of investment generally prevail. Eisenstein makes this quite clear.

It is perhaps to be regretted that the author does not recognize the ideology of "benefits received." My own observations have indicated that this ideology is held by a very large proportion of our people. It is true, however, that it is probably applied to state and local taxes to a much greater degree than to federal taxes; and Eisenstein is obviously much more concerned with federal income taxes than with any other kind. But we still have many millions of people in this country whose strongest feeling concerning taxes is that the government should sell its services in the market, so to speak, and thus that taxes should constitute the purchase price of services rendered by the government, with as much consumer sovereignty as possible.

The ideology of ability to pay presumably has some significant relationship to property taxes as well as to income taxes, but the author makes no mention of property taxes in this connection.

More might have been said about the incidence of the federal corporate income tax. After all, any ideology of taxation should be more concerned about the ultimate burden of taxes than about their first impact. There is much confused thinking (or feeling) at present concerning the shiftability of the corporate income tax.

Everybody who is interested in taxes—and all of us should be, of course—should read this book, even if the sarcasm and the irony become a little wearing at times.

TROY J. CAULEY

Indiana University

Public Finance. By EARL R. ROLPH and GEORGE F. BREAK. New York: The Ronald Press Co., 1961. Pp. viii, 586. \$7.50.

To satisfy minimal contemporary requirements for a textbook in public finance is not an easy assignment. The volume must cover in depth and scope a set of topics—including institutional and descriptive material, history, theory, and empirical knowledge—that could be expanded into an encyclopedia. Moreover, the style should be readable and, if possible, provocative to compete with television, popular magazines, automobiles, and other diversionary influences in modern collegiate life. In this remarkably lucid volume, Professors Rolph and Break judiciously combine these required ingredients in a way that introduces public finance as an interesting and respectable branch of economics.

Oriented toward U.S. experience, with brief references to other countries, the book is in four parts. The first, covering 18 per cent of the main text, defines the subject, surveys the historical development of governmental finances, outlines the meaning of fiscal effects, explains the budgetary process and information available for administrative control and economic analysis, and offers forthrightly some value judgments useful in assessing financial policies. Part II, comprising 44 per cent of the book, examines administration, equity, and economic effects of various tax forms: personal income, spendings, net worth, corporation income, excess profits, death, sales, and commodity taxes. About 19 per cent of the volume is devoted to pricing and investment policies of government enterprise, social security, intergovernmental fiscal relations (including foreign aid and overlapping taxes), and the economics of metropolitan living in Part III. The concluding part, again about 19 per cent of the book, examines fiscal policy, including taxation, expenditures, and monetary and public debt management. At the end of each part, there are bibliographies with brief and useful comments on the content of references. Footnote citations to both early and recent research are scattered through the book.

The authors emphasize analysis of financial policies, with theory, statistical material, and description admirably proportioned to support the argument. A wide-ranging use of analytical concepts from national income accounting, microeconomic theory, aggregative theory, and monetary theory should please

good undergraduates, who often find applied economics inexplicably divorced from analysis, and the average student should have no trouble in understanding the analysis, though occasionally he may be challenged. For a one-semester course, the main text of 558 pages is short enough to permit additional reading in supplementary sources, and yet sufficiently long in content and diversity to serve, if necessary, as the only reading material.

On the whole, the analysis is careful and straightforward, and readers will obtain an increased awareness of the complexities involved in tracing the effects of fiscal policies. This reviewer liked especially the differentiation of the effects of taxes, expenditures, debt, and loan, guaranty programs; the description of information available on taxes and expenditures, and its uses in economic analysis; the discussion of economic effects of the individual and corporate income taxes; the comparison of different types of sales taxes in use; treatment of property taxation; analysis of government enterprise; and the handling of public debt management.

However, there are some unsatisfactory, even erroneous, passages which prevent this reviewer from bestowing uninhibited praise. In discussions of the burdens imposed by various fiscal policies, the relations among money burden, real burden, and shifting are often not clear—as in the treatment of personal income tax incidence (pp. 166-68), excise and sales tax incidence (pp. 290-95), and burdens of public debt expansion (pp. 548-54). Though it is refreshing to find critical analysis of the popular view that excises burden only the consumer, the emphasis is carried too far and leads to erroneous conclusions, in this reviewer's opinion. For instance, the authors' doctrine that selective excises on goods with inelastic demand generate a distribution of burden akin to that of general income or completely general sales taxes, largely because spending shifts away from nontaxed areas to the taxed and thus reduces money incomes of resource owners in nontaxed areas (pp. 290ff., 302-7), is not a correct description of incidence in long-run equilibrium. In the new equilibrium, prices of taxed goods will exceed factor cost prices by the amount of tax per unit; though adjustments to the tax may depress unit money factor costs (market prices) in nontaxed areas, the same forces will lower unit money costs in taxed areas, and by almost the same degree under the postulated conditions. The relative price structure that emerges throws, for the most part, the tax-induced real-income losses on consumers of the taxed items, as traditional theory correctly concludes. The authors' preference for examining consumption rather than saving impacts of fiscal policies is so stated as to suggest that analysis cannot meaningfully be carried out in terms of saving (pp. 180-82). This is likely to be misleading and confusing to the student who learned (correctly) in other books that income determination could be examined either from the expenditure side (consumption + investment + government) or the saving-investment equality (investment + government expenditures = private saving + net taxes).

On the whole, the editorial job of checking errors is well done, but there are a few unobtrusive slips that ought to be corrected by potential users. Employer contributions to retirement plans, but not employee contributions, are deductible from taxable income (p. 123). The table and text on page 185

apparently contain arithmetic errors on the liability from a spendings tax. Maximum effective rate of the Second World War excess profits tax was 72.8 per cent (p. 249). Some puzzling arithmetic is presented in the foreign exchange example on page 320.

Users of this volume, including those who may not agree with the authors' analysis on all points, will find it sprightly in style, forthright in judgment, perceptive in argument, and challenging in ideas. Those who teach from this book will undoubtedly find students eager to discuss and to examine problems of public finance.

CHALLIS A. HALL, JR.

Yale University

International Economics

Coexistence: Economic Challenge and Response. By HENRY G. AUBREY, with the assistance of Joel Darmstadter. Washington: National Planning Association, 1961. Pp. xiv, 324. \$5.00.

This timely study is a detailed investigation into the nature and implications of the competitive challenge to the West posed by the Sino-Soviet policy since the mid-fifties of wooing the less developed nations of the world by offers of trade and aid, by use of other economic instruments, and by an intensified propaganda campaign designed to convince these countries of the superiority of the Soviet system. The eighth and final volume in a project on the Economics of Competitive Coexistence set up in 1956 by the National Planning Association, with Dr. Aubrey serving as Director of Research, it brings together the results of the earlier country and area studies and analyzes in broad perspective the coexistence problem as a whole.

The book consists of four parts. There is a review of the needs and aspirations of the less developed countries that have provided the opening for the Communist bloc's competitive moves; an exploration of the competitive capabilities of the industrial countries of the East and West to cater to those needs through trade and aid; an evaluation of the techniques used by each side and of their economic and political impact; and an outline of the broad policy alternatives facing the West. The chief merit of the book lies in its careful organization and interpretation of a mass of statistical and factual data drawn from a wide variety of sources, and its clear articulation of the nature of the challenge faced.

The author is at his best in those chapters, covering almost half of the book, that deal with the nature and impact of the techniques and instruments of competition that have been used by the Communist bloc vis-à-vis the underdeveloped countries. By well-timed offers to make bulk purchases of excess supplies of primary products and to extend financial aid and technical assistance, by concentrating its aid and trade in key neutralist countries, by its ability to make quick decisions and to implement them speedily, by effectively combining aid and trade in single packages, by extending specially favorable loan repayment terms, by focusing on the financing of "growth-symbolic" projects, and by other such devices, the Communist bloc, despite

the relatively small amount of its aid and trade to date, has been able to exert a disproportionately large psychological-political impact on the less developed countries. Totalitarian decision-making, centralized control of resources, and state trading thus give the bloc some strategic advantages in foreign economic policy not possessed by the West. At the same time, by emphasizing its own rapid rate of growth and by challenging to outstrip the West in per capita industrial output, by playing upon prevailing anticolonial prejudices and by exploiting real or imagined economic grievances in the underdeveloped countries, and by skillful propaganda designed to downgrade the efficiency of the economic system of the West and to impute sordid motivations to its foreign economic policies, the Sino-Soviet bloc has been working with some success to convince the less developed nations that the Communist system is the only model for the rapid achievement of their national economic aspirations. While the author calls attention to some of the mistakes and failures of the bloc and to some of the special advantages possessed by the West, the dominant stress in these chapters is on the advantages on the Communist side—so much so, in fact, that one gets the impression of some degree of overstatement.

Less satisfactory and conclusive is that lengthy part of the book dealing with the present and longer-run competitive economic capabilities of the East and West for aid, trade, and economic growth. In five successive chapters, which examine the problem from the viewpoint of the Communist bloc, Western Europe, the United States, Japan, and the Free World as a whole, Aubrey compresses a good deal of useful information and makes some shrewd observations relating to growth rates, balance-of-payments trends and economic developments, and the factors affecting trade and aid potentials and prospects, in each of these countries and areas, without reaching many clear-cut conclusions regarding what he set out to ascertain. His essential conclusions seem to be that the decisive factor in the amount of assistance given or to be given to the underdeveloped countries is not "abstract capabilities," but the will to release resources in the light of competing claims upon those resources for domestic purposes; and that both sides could "afford" to give much more than at present without undue strain if they wanted to or had to. In any case, he says, what seems to matter most is not the absolute magnitudes of aid or trade per se but the resulting impact on the minds of the less developed countries. Do these conclusions justify the lengthy discussion?

The policy conclusions are disappointingly brief and general, although it is stated that the purpose is not to make concrete recommendations. Contending that the West's policy towards competitive coexistence has thus far been largely reactive rather than initiating, the author argues that the challenge should be met by greater cohesion and cooperation among the leading countries of the Free World, and by more flexibility and adaptation in policy, in helping not only each other but also the underdeveloped countries to raise their living standards within a democratic framework. Attention is called to some of the desirable areas for cooperation, e.g., in assuring more stable markets for primary-product exports and in enlarging the flow of foreign aid,

and to some of the institutional mechanisms through which it might be made more effective. But Aubrey's main point here seems to be that a more positive long-run Western foreign economic policy—looking beyond the competitive challenge and worthy of pursuit even in its absence—is called for in place of the present negative focus on defence and military objectives. More specifically, world economic development should be recognized as a primary objective of our policy and aid should be given for the sake of development as such, not for competitive reasons. Apart from its favorable psychological impact on the minds of the recipient countries, such a policy, according to the author, would break the vicious circle of bloc initiative and overly reactive response on our part.

There is some overlapping of material in the various chapters, an unnecessary amount of repetition, and a measure of obscurity in some of the arguments and conclusions. But none of this detracts from the fact that Aubrey's study is a stimulating piece of work and an important contribution to the political economy of competitive coexistence.

ARTHUR I. BLOOMFIELD

University of Pennsylvania

Business Organization; Managerial Economics; Marketing; Accounting

The Theory and Measurement of Business Income. By EDGAR O. EDWARDS and PHILIP W. BELL. Berkeley: University of California Press, 1961. Pp. xv, 323. \$7.50.

The methods developed by these authors for reporting the income and financial condition of a business in more meaningful terms but without eliminating the traditional income statement and balance sheet give a basis for a significant advance in the techniques for accounting reporting. This advance would bring accounting more in line with economic thinking and if adopted would ultimately, I think, bring economic thinking on profit maximization more in line with measurable concepts of profit.

The authors construct several concepts of profits which are measurable in the objective accounting sense and are related in a simple way to profit as currently reported under the most orthodox accounting procedures. One of these concepts denominated "real business profit" is presented as a close approach to, or at least a good proxy variable for, what the authors' consider the dominant economic concept of profit.

Part II presents the procedure for developing six interrelated but significantly different concepts of profit. These concepts may be developed from the usual bookkeeping data by means of end-of-period adjustments that are not unduly complex. The six concepts of profit and the appropriate balance sheets can all be presented in an integrated form that should be very useful both to management and to outside analysts. The most highly questionable adjustment, perhaps, is that based on "current costs" of fixed assets, but, granted that the difficulties involved in getting such a current cost are great,

one must also grant the validity of their argument that reports based on an informed estimate are better than reports which simply ignore the effect of changes in such current costs.

The sort of reports suggested in this volume could be so valuable to businessmen, accountants and economists that I regret the necessity for pointing out some serious shortcomings of the book.

Unfortunately the book puts its worst foot forward. Only in the third chapter does the book get onto solid ground. Highly questionable ideas that are unessential to developing the theme of the book are expounded in the first chapter in a way that seems almost designed to alienate both the economists and the accountants the book should reach. The third paragraph introduces the stationary state in one of its more extreme varieties and in subsequent pages present-day accounting procedure is adjudged to be "valid," "truthful," "correct," "accurate" only if it assumes "a situation clearly akin to the stationary state." Immediately after this almost emotional development of the dubious accusation that "accounting assumes . . .," and the proliferation of adjectives of value judgment, the same points are made adequately and acceptably in terms of their representing certain accounting conventions.

Later in the first chapter (pp. 16 ff.) the attack on the usefulness of general price level adjustments of accounting statements overreaches itself, culminating in the indefensible statement that:

if management feels that the retention of profits will serve the best interests of owners better than its disposition in the form of dividends, changes in the price level will not in themselves affect the correctness of this decision.

Part of the trouble is an assumption that there is a correct or true method of reporting and many incorrect methods whereas the issue is really one of more or less appropriate and useful definitions. Fortunately this assumption is confined to the early part of the book and does not affect the substantial contributions made later.

The discussion of subjective value and subjective profit in Chapter 2 leaves much to be desired. Although the route taken is questionable, the conclusions that subjective profit "cannot be measured objectively" and that "even its subjective measurement normally cannot be accomplished until the firm's plan of operation has already been revised" (pp. 43-44) seem to be sound and to provide a sufficient basis for development of the authors' thesis that only under an alternative definition can profit be measured objectively. But the attempt to show that maximization of the suggested alternative, realizable profit, is equivalent to maximization of subjective profit is, I believe, unsatisfactory.

At the practical level I find only one aspect of the book unsatisfactory, the obliquely suggested tax implications. By presenting examples in which it is shown that if all holding gains are taxed at the present capital gains rate, taxes are reduced, a tacit endorsement of such treatment is implied. Since the authors specifically avoid discussion of the validity of special capital gains rates for their categories of profit they should avoid any suggestion, specific or implied, that their methods reveal a case for tax-law changes which would lower the taxes of many businesses.

The bibliography is voluminous including some material of very doubtful relevance (e.g., a little piece by the reviewer) but unfortunately it omits such an important piece as J. Hirshleifer's "On the Theory of Optimal Investment Decision," *Journal of Political Economy*, August 1958.

In general, the authors make a solid contribution to the task of developing better profit concepts. The book suggests what seems to be a good framework for more useful accounting reports in spite of the fact that, in the reviewer's opinion, it fails to provide the theoretical foundation the authors seek for their concepts. The suggested methods can and should stand on their practicality and on the light which reports prepared on this basis would throw on the activities and position of a business. We can only hope that readers will by-pass the book's weaknesses and accept its practical contributions.

CALEB A. SMITH

Brown University

• **Industrial Organization; Government and Business; Industry Studies**

Workable Competition and Antitrust Policy. By GEORGE W. STOCKING. Nashville: Vanderbilt University Press, 1961. Pp. vii, 451. \$7.50.

Professor Stocking, past president of the American Economic Association and long-time student of antitrust policy, reprints in this volume ten papers originally published during the 'fifties as a prelude to the publication of his comprehensive new book, *The Evolution of Antitrust Policy*.

Because these essays are so closely related as to be variations on a single theme, I shall not attempt to review them individually. The first and last are the presidential addresses to the Southern Economic Association (in 1952) and the American Economic Association (in 1958). Of the remaining eight, five appeared in law journals, two in the *Antitrust Bulletin*, and the remaining one in the *Journal of Business* of the University of Chicago.

The major purpose which this volume serves, aside from the stated one of satisfying the many demands for reprints of the individual articles, is to illustrate the nature of the Stocking creed, to show how its neglect has led to errors of administration and policy, and to provide a simple guide to future policy. To imply, as I suspect I am doing, that Stocking is a propagandist or missionary (albeit for a cause that many will feel is both right and righteous) should not detract from the fact that he is a scholar whose reading of both legal and economic sources is comprehensive and acute. But, as Stocking says of Judge LaBuy (in criticizing his decision in the *Du Pont* case), "what the record discloses . . . depends as much upon the preconceptions of those examining the facts as on the facts themselves" (p. 323).

The Stocking preconceptions may be summarized as follows:

1. Power is abhorrent in a democratic society. Fewness of sellers—concentration—breeds market power, whereas competition restrains it. Power should be curtailed and competition fostered at every opportunity.
2. This view, clear enough to the framers of the antitrust laws has not prevented the growth of power in the form of big business, big unions and

other power blocs in our economy. This is due in large part to the fact that the clear, simple and honest insight of the Sherman Act was emasculated by the apparently plausible but actually insidious legal doctrine known as The Rule of Reason which removed oligopolistic aggregates of power that were not predatory from the scope of antitrust prosecutions.

3. Workable competition, if interpreted to focus on performance, is an equally dangerous modern doctrine and one that economists have unwisely although successfully pressed upon the courts. This doctrine has provided an institutional basis for lax administration of the antitrust laws and it has encouraged a rationalization of the *status quo* (p. 383). Workable competition is a treacherous guide to public policy when set up as a standard by which to judge an industry's performance (p. 69).

4. "The object of an appropriate performance test *should be* merely to determine whether an arrangement is consistent with competition" (p. 262). "While economists now look to effective or workable competition to regulate economic activity, *most of them* would recognize as effective only the kind of competition in which resources are allocated in response to independent decisions of rival business firms *none of which has any considerable power over the market*" (p. 195, emphasis supplied).

These essays in addition to a careful if somewhat repetitious exposition of this standpoint, survey past and present activities in various ways. (a) The evidence in a number of major antitrust cases is reviewed (steel, cellophane, tin cans, and DuPont-General Motors receive major attention) and Stocking concludes in *every* case that, by his standard, the industries were not workably competitive. The court erred, not merely because in some cases it failed to find violations of statute, but because it chose a different, more sophisticated, yardstick than "whether a combination hinders the operation of market forces." (b) Stocking reviews ten cases of trade association activities and finds the court reached the wrong decision only in the three cases where the charges were dismissed. (c) He reviews the report and recommendations of the Attorney General's Committee and finds repeatedly that they have missed the opportunity to strengthen antitrust enforcement because they fail to appreciate and adopt the Stocking position. (d) Jointly with W. F. Mueller, he reviews the practice of reciprocal buying by large corporations and concludes that (since it limits competition) it is inconsistent with workable competition.

The trouble with Stocking's essays, in my view, is that they will only persuade the persuaded. I suspect that the courts, and many—perhaps even "most"—economists, lawyers, and others interested in public policy toward industry, do not act as Stocking believes they should, not because they have failed to hear his plea, but because they do not accept it. "Determining whether an arrangement reflects or interferes with competition is not always easy, but it is easier than determining whether an arrangement that interferes with competition promotes the general welfare" (p. 70). Stocking draws comfort from this observation, others do not.

The Control of Monopoly in the United Kingdom. By PAUL H. GUÉNAULT and J. M. JACKSON. New York: Longmans, Green, 1960. Pp. ix, 197. \$6.50.

The Antitrust Laws of the United States of America. By A. D. NEALE. New York: Cambridge University Press, 1960. Pp. xiii, 516. \$7.50.

Since the war the British have begun to experiment with antitrust legislation and there has, accordingly, been an upswing of interest in the United States experience. These books describe the administration of antitrust laws in the two countries and are intended for the nonspecialist British reader. They are not addressed to economists, and the authors do not undertake the economic analysis of monopoly problems, but they attempt to summarize the opinions of economists on the issues of public policy that are involved.

The British antitrust machinery was very thoroughly revised in 1956. Guénault and Jackson deal mainly with the earlier experience under the act of 1948, devoting only 21 pages to the 1956 legislation. The book is therefore mainly of historical interest.

British legislation has been based on the view that there is not a sound theoretical case against monopolistic practices, and accordingly the law should not treat them as illegal per se. Hence the legislation requires investigation into the specific circumstances of each case before the practices employed can be banned. Guénault and Jackson share the official skepticism of theoretical conclusions but argue, as Neale does also, that there is a case against restrictive practices on "empiric" grounds.

Their informative and well presented account of the British legislation and its administration brings out clearly the inadequacy of the British approach. Case-by-case investigation cannot of course do justice to the interdependent character of the economy. Nevertheless the commission sitting under the 1948 legislation concluded its cumbersome investigations with the finding that a wide range of practices were in general against the public interest and should be prohibited, with provision for exceptions in special cases. The 1956 legislation watered down this recommendation, requiring condemnation by a Restrictive Practices Court before an agreement or practice can be banned in each particular case. The authors rightly criticize the legislation as an "inadequate and hesitant approach."

Neale presents a longer and more thorough analysis of American antitrust administration. The book is one in the series Economic and Social Studies undertaken by the National Institute of Economic and Social Research in London. The emphasis is on legal and administrative problems rather than on economics, and the author has done an admirable job of distilling the "real" meaning of antitrust from the history of judicial interpretations, to which the bulk of the book is devoted. The legal bias leads to some awkwardness in the organization of the book. Readers interested in mergers, for example, will have to look in three different sections. Other topics, however, such as agreements, price discrimination, and resale price maintenance are each given a unified discussion. Economists will find in this book an excellent guide to the shifting trends in judicial thinking and interpretation.

The penultimate chapter contains a very good summary of the main

intellectual and political sources of antitrust policy, and a not-so-successful attempt to assess the "effectiveness" of the antitrust laws. The suggestion that "nobody now expects in the United States to get away with overt price agreements or any of the obvious variants such as agreements for level tendering, formula pricing and so on" seems overoptimistic in the light of recent cases.

In the final chapter the case for competition and for the suppression of anticompetitive practices is rejected on theoretical grounds but accepted on "empiric" grounds. The notion that one's own brand of arm chair theorizing is "empiric" is an amiable British foible.

Vertikale Preisbindung in der Markenartikelindustrie. By HERBERT HAX.
Köln and Opladen: Westdeutscher Verlag, 1961. DM18.50.

The marketing policy of vertical price agreements has been the subject of much debate here and abroad. In view of the volume of contributions made in both hemispheres one would hardly expect further amplification in this field of inquiry. Yet, it is evident that Dr. Hax has a profound knowledge of the subject and an unusual insight into the motivating *modus operandi*, coupled with the gift of original thought and vigorous expression, so that his book offers a contribution to the general line of thought. The purpose of the publication is not so much to broaden the admitted field of controversy but rather to examine the polemical discussions and to explore those which lack objective and methodical argumentation.

In general, Hax undertakes the formidable task of inquiring into the basic, impelling motives that actuate decisions designed to lead to the most profitable alternative from the producers' viewpoint, and into the impact such decisions are likely to have not only on the individual enterprise but on the total economy. The author stresses ad infinitum the importance of reaching conclusions only on the ground of socio-economic justification. The fact that 493 footnotes and references support the work indicates that a genuine effort was made to summarize and systematize arguments heretofore presented and to arrange them on comparative scale. Admittedly, however, empirical material was considered of only secondary importance in presenting the evidence.

The text is arranged in five divisions with the first chapter devoted to a 26-page introduction which deals with the definition of vertical price agreements, their impact on competitive behavior, quality guarantees, marketing efforts, and profit margins.

Part II presents by far the major portion of the work, dealing as it does with the problems of how far and for what purpose the producer can use a policy of vertical price agreements in marketing his product in an effort to extend his share of a dynamic market. Price agreements and their controversial aspects are reviewed here, especially as they pertain to the media used for distribution, profit possibilities, "formulated" marginal income

concepts, quasi-cartels, the effect of selective price concessions and alternative pricing policies. Hax concludes that the necessity for a policy of vertical price agreements as a tool against price differentials in a free marketing economy is hardly substantiated. The effect of vertical price agreements as related to competition among rival producers is also further examined in this part.

Parts III and IV consider the more specifically vertical price agreements in their relation to the trade and the consumer respectively. Regarding the former, special emphasis is given to the general uniformity of profit margins and the relationship of this uniformity to competitive distribution efforts, special problems of jobbers and wholesalers, and the purpose and enforcement possibilities of pricing agreements. Observations on black-market tactics and appeals for "bargaining" as an aspect of less refined standards of a moral society are by-products of the discussion.

Part IV explores the topic from the consumer's viewpoint; e.g., protection against excessive prices, the impact a stabilization of prices may have on the total economy.

The author summarizes his work by evaluating the data and by relating them to current German laws and regulations. As part of the concluding remarks the text reviews existing legal restrictions and comments on "price recommendations" as contrasted to "price agreements," quoting a Supreme Court (*Bundesgerichtshof*) decision that price recommendations cannot be considered different from price agreements.

The Germans have a reputation for unusual industry and thoroughness, of which this book is characteristic. The writer has done a thoughtful piece of work and, apparently, has no one-sided theories to advocate. No one interested in the subject could fail to profit from this publication. It is much more than a mere synopsis.

Its scholarly contribution to this so controversial subject merits consideration especially by those who are responsible for the formulation of restrictive legislation, and those engaged in research.

University of Detroit

Electric Utilities—Costs and Performance. By WILLIAM IULO. Pullman: Washington State University Press, 1961. Pp. viii, 180. \$7.50. Statistical Appendix, 82 pp., \$10.00.

The nature of this volume is indicated by its subtitle, "A Study of Inter-Utility Differences in the Unit Electric Costs of Privately Owned Electric Utilities." The study is said to have three major purposes. One purpose is "to investigate the quantitative relationships that exist among the various factors that, either by tradition or logic, are believed to affect the unit costs of providing electric energy. . . . Such information, when combined with a utility's knowledge of its own special circumstances, would be of value in such areas as the designing of sales promotion efforts and the guiding of technical

and administrative research programs" (p. 3). A second purpose is to develop a measure of the ability of the various factors, singly and in combination, to explain the variation in costs among different utilities. By comparing the actual unit costs of a utility with the sum of those unit costs which reflect factors that are relatively immune to managerial control, light is thrown on the relative efficiency of the managements of the different companies. A third purpose is to aid in improving the statistical information compiled by regulatory agencies by calling attention to the factors which are and those which are not significant in explaining the performance of the utilities.

The companies studied were privately-owned operating utilities which generated at least part of the power which they distributed to a broad range of users. Companies were excluded which generated less than 10 per cent of their total kilowatt-hour sales, or which generated over half of their power by internal combustion equipment, or which did not sell power to both residential and commercial and industrial users. The number of utility companies included was 60 per cent of all Class A and Class B electric utilities, representing 87 per cent of all kilowatt-hour sales and 93 per cent of all customers. Class A and Class B utilities in turn represent 98 per cent of the privately-owned electric utility industry on the basis of assets and revenues. In computing costs all the usual items were included, except that rate of return on capital was not included as an expense. The period covered by the analysis, which was governed by the availability of data, was 1952 to 1957 inclusive.

The author considers at length some thirty factors which might have a significant bearing upon electric utility unit costs. In order to minimize the element of personal evaluation multiple regression analysis was used to determine which of these factors actually had a significant bearing upon unit costs and to arrive at an estimate of what the unit costs of the utilities would have been if all of the factors had operated with equal force on all the utilities studied. The seven factors found to be significantly related to electric utility unit costs were: the size of the steam-electric generating stations, capacity utilization, the level of steam-electric fuel costs, the level of hydro-electric "fuel" costs (i.e., the cost of providing for water storage, analogous to the cost of providing fuel storage for steam-electric plants), distribution of the market among customer classifications, average consumption of energy per industrial and commercial user, and average consumption of energy per residential user. In combination with one another these factors, which the author classifies as relatively insensitive to managerial control in the short run, were found to account for approximately 80 per cent of the interutility differences in unit costs. It was also found that unit costs were little affected by the geographic location of the utility or by the use of hydroelectric as compared with steam power. By comparing the actual unit costs of the companies with the unit costs estimated on the basis of multiple regression analysis, using the seven factors listed above, the author is able to group the companies according to their relative efficiency. The basis of the grouping is admittedly arbitrary, about one-sixth of the companies being classed as very efficient, one sixth as inefficient, and the remainder as normally efficient. A separately-

published appendix contains details of the unit costs of the individual companies.

The reviewer is unable to pass upon the technical aspects of the statistical analysis but his impression is that the work was carefully done and that the limitations both of the analysis and of the data used were adequately recognized. In any event the study deserves recognition as a pioneering contribution to the establishment of standards of efficiency—an important and seriously neglected part of the task of public utility regulation.

ROBERT W. HARBESON

University of Illinois

The Economic Value of the United States Merchant Marine. By ALLEN R. FERGUSON, EUGENE M. LERNER, JOHN S. MCGEE, WALTER Y. OI, LEONARD A. RAPPING, and STEPHEN P. SOBOTKA. Evanston: The Transportation Center, Northwestern University, 1961. Pp. xxii, 545.

For at least three reasons, this is an interesting book. The quality of its research is high indeed; it is a fine example of fruitful, so-called "team research"; and it demonstrates that a study, requested and financed by people who no doubt hoped for findings favorable to their interests, can and will be published despite conclusions damaging to their position. Both the Transportation Center at Northwestern University and the Committee of American Steamship Lines (the financiers) deserve congratulations upon the publication of this book.

For many years, some advocates of a subsidized merchant marine for the United States have claimed that, aside from its value as the "fourth arm" of national defense, the subsidized merchant fleet makes a significant economic contribution to Americans. They have no doubt been annoyed by the summary dismissal of this contention by those who merely point to the necessity for payment of a subsidy as sufficient proof that the industry makes no economic contribution within the generally accepted meaning of that term.

Ferguson and his associates certainly cannot justifiably be accused of undue brevity or superficial analysis in their assessment of the economic value of the American-flag merchant marine, even though they confine their study primarily to the subsidized ocean liner industry and exclude the military value of the merchant marine from their definition of economic value.

At the beginning the authors point out that though there is a variety of "possible or asserted benefits" attributable to its existence, the subsidized merchant marine makes an economic contribution only if the value of its output is "greater than the value of the best alternative use of the resources used to produce that output." Since the industry is subsidized because costs exceed revenues, the merchant marine therefore makes an economic contribution only if the value of its output sufficiently exceeds that indicated by the earnings statements of the subsidized companies. Ferguson and his colleagues thoroughly search for evidence of this excess value.

In the course of their investigation the authors describe the industry and the federal maritime program, analyze the costs of shipbuilding and of vessel

operation and the impact of the differential subsidy program upon these costs, examine the competitive structure of the markets for shipping services, study the operation and rate-setting practices of shipping conferences, consider other ways of establishing rates, and estimate the effect of the reserve fleet upon shipping rates.

In a properly cautious summary statement of conclusions, the authors note:

Thus, briefly, there appears to be little net economic contribution to the United States by the subsidized liner firms or deriving from the subsidy program. The operation of the reserve fleet in mitigating shipping crisis is the only major exception to these gloomy conclusions. Their validity is, of course, subject to any imperfections in the analysis, to inadequacies of the data, and particularly to the choice of criteria.

For a program costing the federal government about \$120 million annually for operating-differential subsidies and a total (over several years) of \$1.5 billion to \$2 billion for the replacement of vessels, these are certainly "gloomy" conclusions.

The well-substantiated findings of the authors indicate that trade development activities of the industry "generate no significant economic values." They also conclude that the existence of the American-flag subsidized merchant fleet does not result in lower shipping rates, and therefore "does not make a major economic contribution as defined in this study." This leaves the depressive effect upon shipping rates occasioned by activating ships in the reserve fleet during periods of great demand for shipping services as the important economic contribution of the maritime program of the United States.

No doubt many people in the shipping industry and perhaps some students of maritime affairs will be disturbed by this study. Yet, unless they are unable, for whatever reason, to accept the authors' definition of economic contribution, the limits of their study, and their competent employment of analytical techniques, they will probably grudgingly admire the research reported in this book.

Land Economics; Agricultural Economics; Economic Geography; Housing

Agricultural Production Functions. By EARL O. HEADY and JOHN L. DILLON. Ames: Iowa State University Press, 1961. Pp. vii, 667. \$6.95.

With problems of growth and technological change moving to the forefront of professional interest, there has been a resurgence of interest in production functions on the part of general economists. But while production-function research was out of fashion on a national level, it led a very vigorous life among agricultural economists. The volume under review, besides being a text on the theory and methodology of agricultural production-function fitting, is also an encyclopedia of previous research results in this area. As such it should prove useful to all economists interested in problems that are or can be put into a production-function framework.

There are at least two different kinds of production-function work going on, each with its own methodological problems. The first kind is the normative "engineering" approach: the economist as an advisor to a farmer or businessman is called upon to prescribe *the* "optimal" resource combination (e.g., the economically optimal level and mixture of fertilizers to be applied on a particular crop in a particular area). To do this he has to know something about the characteristics of the technical relationship but usually only over a very small section (or only for a few of the many dimensions) of the "global" production function. Unfortunately, the agronomists or engineers have rarely collected data on physical response relationships in a form suitable for economic analysis and prescription. Thus, the agricultural economist finds himself involved in designing essentially agronomic experiments to get at the necessary information for specifying what is the optimal level of nitrogen use on corn at a given corn-nitrogen price relationship. Such "physical" production functions have been estimated from various fertilizer and animal-feeding experiments and the results have been used to recommend to farmers how they should improve their practices. These results have been particularly useful in educating agronomists to appreciate the importance of price relationships.

While the first type of production-function research uses experimental data and only a few well-defined inputs (such as a specific mixture of protein feed), the second type of production-function research is descendant from the Cobb-Douglas tradition, utilizing data generated by actual economic units, and working usually with several ill-defined aggregate inputs such as "labor," "machinery," "current expense," and others. This type of production function has been used by agricultural economists to analyze the relative productivity of different resources in agriculture, to diagnose various "disequilibria," to search for evidence of economies of scale, and to prescribe "optimal" crop and input-use patterns for farms in specified areas or size classes. The data for this type of analysis have come largely from farm accounts or from special cross-sectional surveys. This type of approach has not been used often, however, as a tool of economic history, where it could be used to try to explain how and why certain things happened and how they may work out in the future. It is this latter use that has led to the general revival of interest in production functions.

The book itself deals mostly with "physical" production functions. This is as it should be, since this is the area where the agricultural economists have made their largest contribution; but it does reduce the book's interest to the general reader. The book is divided into four parts: the first 100 pages introduce the economic theory and the mathematics of production functions and their general use in economics. The next 150 pages are a small textbook in the econometrics of production-function fitting. The third and largest part of the book, close to 300 pages, brings together a large number of physical production-function studies, mainly by Iowa State economists, dealing with feed-weight gain relationships for hogs, poultry, and beef, marginal rates of substitution between forage and grain in milk production, and crop-fertilizer response "surfaces." The fourth and last part of the book, about 100 pages, discusses the estimation of cross-section farm production functions using non-

experimental data and summarizes a large number of such studies from all over the world.

The statistical methodology section of the book covers a very wide range of subjects, from the definition of variance through regression, design of experiments, confluence analysis and more, doing a good if superficial job of it in very short space. It is marred, however, by several erroneous or careless statements: There does exist a transformation to a form linear in the parameters for the multivariate logistic function—the logit transformation (p. 126); autocorrelation in the *variables* does not bias the estimated variances of the coefficients (p. 131); autocorrelation in the residuals does not lead to a bias in the coefficient estimates if everything else is all right (p. 133); it is not necessarily “desirable that the coefficient of multiple determination, R^2 , be as close to unity as possible” (p. 210). In the sections on estimating various optimal feeding formulas too much stress is put on testing the statistical “significance” of certain coefficients of the estimated production function and almost none on testing the statistical and economic “significance” of the prescriptions. What is the “standard error” of the calculated “optimum”? And even if the confidence interval around the “optimum” is quite narrow, the difference in profits between optimal and nonoptimal points on the production function may be quite small.

In general too little testing has been done of the economic conclusions of production-function fitting. Most of the research just summarizes a piece of data without testing the conclusions on new or different data. In particular, if the profit maximization hypothesis is accepted, the prescriptions are also predictions. Thus, if a particular feeding or fertilizing combination is adjudged to be optimal, we should observe farmers moving in the direction of this technique. If they don't it could be that they are ignorant or irrational but it also could be that the prescription is wrong, being based on a wrong or incomplete model. Similarly, a finding that the marginal product of labor is substantially below the going wage rate is also a prediction of occupational out-migration. None of these studies, however, follow up their prescriptions-predictions.

The basic problem in interpreting the results of nonexperimental firm production-function fitting is in the specification of the economic model that generated these data. If all firms (farms) in an area are faced with the same factor prices, have the same production function, and maximize their profits, they would all use the same combination of resources and we could not estimate a production function. Obviously, they do not all use the same resource combination, but why? Maybe they do not maximize profits, but then they don't have to be *on* their production function. Maybe they all have different production functions—but what is the sense then of estimating one production function for all of them? They could be faced actually with different prices—but then we should use this price information and estimate the structural production function from the reduced form equations (factor demand functions) with prices as exogenous variables. Alternatively, different farmers may form their expectations differently and thus wind up at different points on the production function even though the objective information is the same for all

of them. But without specifying explicitly what produces the observed data, it is impossible to draw any "structural" conclusions from nonexperimental data. It is surprising that in a book of close to 700 pages only one short paragraph is devoted to the possibility that what the book is trying to do cannot be done at all a priori, or at least cannot be done in the way it is going about it.

ZVI GRILICHES

University of Chicago

Agricultural Supply Functions—Estimating Techniques and Interpretation.

Edited by EARL O. HEADY, C. B. BAKER, HOWARD G. DISSLIN, EARL KEHRBERG, SYDNEY STANFORTH. Assembled and published under the sponsorship of the North Central Farm Management Research Committee. Ames: Iowa State University Press, 1961. Pp. viii, 305. \$3.95.

"Dedicated to the proposition that progress is made by discussing hypotheses, theories, techniques, and illustrations of their use even though some are still in their formative stages," this book is an outgrowth of a conference in January 1960. The resulting 17 papers and 16 discussions are organized into six sections: introduction; regression analysis of aggregative, time-series data; supply estimates derived from individual farm data; regional competition and spatial equilibrium models; interpretation of supply functions; and summary. The theme throughout the volume is the estimation and interpretation of the genus often referred to as statistical supply functions. This is a logical sequel to earlier preoccupation with statistical production functions.

Although the subject of some research more than three decades ago, agricultural supply has begun to receive intensive empirical investigation in recent years. There are now many advocates of the view that failure to deal with "the farm problem" in a satisfactory fashion is due in large part to a lack of knowledge concerning agricultural supply behavior and its basic determinants in our changing economy. In the lead paper in the book under review Heady states, "Directly, the major problems of American agriculture are those of supply."

The current focusing on agricultural supply is another strap in the harness used by institutionalized agriculture to bridle the beast, "the farm problem." Earlier attempts included battling the trusts, cooperative purchasing and marketing, restricting supply, relying on a healthy and growing general economy, expanding exports, and creating the so-called soil-bank.

Both the nature and the scope of research devoted to the understanding of the behavior of agricultural supply is reflected in the contents of this book. Whether the bridling is to be effective cannot be known at this stage of its development, but the dedicated and serious efforts of the authors of this book and other researchers in this area cannot be questioned. General agreement emerges as to the nature of the problems and the gaps remaining. These difficulties are mentioned to an annoyingly repetitious extent in the various papers: the complex structure of agricultural production; the lack of an adequate theory of aggregation of firm supply functions; the absence of an appropriate theory of firm behavior under uncertainty; the need for an em-

pirically useful theory of the variation of fixed and quasi-fixed factors over time; and the lack of an operational theory, with related measuring techniques, for the investigation of technological change and its impact on the operations of the firm.

But these gaps and problems are not limited to agricultural supply analysis. They also confront the general economist when he leaves the classroom and undertakes empirical research on the supply side of the firm and industry operating in our changing economy.

The shortcomings of the widely-used multiple regression estimation technique in agricultural supply analysis are also repeatedly emphasized in a number of papers in the book. Aside from the usual limitations, this method is held particularly inadequate in the handling of structural change. The dramatic alterations in the structure of agriculture in the past two decades have led the authors to emphasize this inadequacy. It might well be noted that this difficulty also is not peculiar to the analysis of agricultural production and supply. If other segments of our economy had been subjected to as much empirical investigation as has agriculture, we might well be more knowledgeable than we are of the structural complex of the economy at large.

In terms of new ideas and approaches, the volume is not strikingly productive. Two attracted this reviewer's interest: Nerlove's account of Muth's "rational expectations hypothesis," and Richard H. Day's "recursive programming." The latter is a synthesis of time-series analysis and linear-programming versions of production theory. Yet it is to new ideas and approaches that one must look for bridgeheads which may give the foundation from which to traverse the gaps in agricultural supply analysis. The conventional ideas and techniques are too blunt to probe to the heart of some of the problem-areas which the book examines. Involved are a wide range of production-supply activities from the owner-operator in a changing world of uncertainties to the chronic "surplus" situation in major agricultural crops for which we have national legislation and largely ineffective programs.

It is generally agreed that the influences stemming from technological change are among the significant determinants of longer-run agricultural supply behavior. Yet technological change reflects an accumulation of knowledge resulting from a complex of processes we do not comprehend. Halter, in his discussion of the impacts of technology, argues that because the accumulation of knowledge is a unique historical process, any hypothesis formulated to describe it cannot be tested. He concludes that "the impossibility of finding a law of technological evolution" limits prediction to the short-run and a given technological period. This is a less sanguine outlook than in most of the papers giving attention to the impacts of technology.

The essence of the book as a whole is its reflection of agreement on the major gaps and problems in supply analysis, and the present need for much more attention to the development of theory and less emphasis on measurement in agricultural supply analysis. Improved theories are a requisite for improved measurement. General economists likewise have inadequate theories for dealing effectively with technological change, aggregation, investment in

fixed factors, uncertainty and expectations. The complexities that face those working in agricultural supply analysis are no less real because they are part and parcel of the difficulties that confront all economists. But some agricultural economists, at least, are facing up to the problems by attempting to improve both theory and measurement.

SIDNEY HOOS

University of California, Berkeley

Soviet Power: Energy Resources, Production and Potentials. By JORDAN A. HODGKINS. Englewood Cliffs: Prentice-Hall, 1961. Pp. xviii, 190. \$5.25; text, \$3.95.

This little book is essentially a descriptive geography of Soviet fuel resources and production. On the basis of many Russian language sources, the author has pieced together the extent and regional location of Soviet fuel resources. The general picture that one obtains is of a country with vast fuel reserves, of which coal is predominant. Yet the locus of energy consumption is principally in European Russia while the greatest reserves, particularly of coal, are in Northern Siberia. Consequently, energy sources which are less plentiful and more costly but more accessible to the principal consumption centers are being exploited. The coal mines of the Moscow basin and the utilization of shale for fuel in Estonia are examples. Even so, coal is being transported over long distances. The rapid development of the newer energy resources, oil and natural gas, has improved this situation since their production (and *known* reserves) are closer to the centers of industry. They are, moreover, held to be advantageous from the point of view of investment cost and production cost.

A timely title sometimes exposes an author to the risk of disappointing his readers. In this case, the reader's disappointment arises out of the fact that the survey of fuel resources is nowhere related to the issue of Soviet power. The author states at the beginning that "Energy resources and their development are the key to a nation's technical and industrial capacity. . . ." While this notion is referred to occasionally later, there is no consideration of how the growth of the Soviet economy has been affected (helped or perhaps impeded) by its resource availabilities. Nor is there any evaluation of future Soviet needs for energy materials or of the expansion of energy supplies in relationship to the planned development of Soviet productive power. These are serious omissions, since projections which could serve as the basis for such analysis are made available in the Soviet seven-year plan.

The discussion is further marred by several faults. The following are some examples:

There is excessive emphasis on the implications of the resource "potential," the total power-content of all mineable fuel resources. Yet the author recognizes that much of this "potential" is located where there is neither industry nor means of transport, and has little if any relevance now or in the foreseeable future.

Given the tentative nature of any resource reserve estimates, the author

lumps together coal reserves (of which only 3 per cent are proven and the rest are probable and inferred) with "known" reserves of oil and "known" reserves of gas "in fields recently being exploited on an industrial basis." Small wonder, then, that more than 99 per cent of the "energy potential" is found to be in coal!

Soviet exports of petroleum (which are increasingly competing in world markets) are not mentioned. Indeed, the author appears to be unaware of the fact that the USSR has developed rapidly expanding exports of oil or that export pipelines from Russian oil fields to the borders of Western Europe and to the Pacific coast of Siberia are under construction.

This book serves to give a broad picture of the extent and regional distribution of fuel reserves in the USSR.

Labor Economics

Farm Labor in Germany 1810-1945—Its Historical Development Within the Framework of Agricultural and Social Policy. By FRIEDA WUNDERLICH. Princeton: Princeton University Press, 1961. Pp. xv, 390. \$8.50.

This book is an exceedingly careful, detailed and incisive history of the evolution of German farm labor during the nineteenth century and up to 1945. The beginning of the period is the time when serfdom was abolished in the course of the Napoleonic wars. The end of the Second World War provides a natural conclusion to the study. The author, recently retired from the New School for Social Research, is well known for her contributions in the area of German labor relations, particularly her book on the German labor courts.

The period between 1810 and 1918 is treated as a prelude to the real substance of the volume. Some 30 pages are devoted to the entire century up to 1918 while the Weimar Republic takes up 120 pages and the Hitler era no less than 140 pages. Although the 30 page summary of nineteenth century farm labor history is brilliantly written and contains most of the essentials, it is obvious that the book would be more properly described as a history of German farm labor between 1918 and 1945. As such it has great merit.

The Weimar era is essentially the period in which a capitalistic farm labor market emerged among many survivals of a precapitalistic nature. The functioning of the labor market was impaired, however, by the predominance of independent peasant holdings in the West and South, and even more by the survival of large estate owners with their special privileges in the East. The economic decline of the large agricultural enterprises which ceased to be profitable when the great depression set in, set a fateful process in motion, directed at the same time against the market economy and the democratic Republic. When in 1932 Chancellor Brüning decided to discontinue the subsidies of a number of large estates and to use the land for the settlement of small farmers, the Junkers prevailed upon President von Hindenburg to dismiss the Chancellor.

An inventory of the benefits which the Republic bestowed upon the farm workers reveals an astonishing wealth of measures. Among the items that may surprise the U.S. reader are compulsory sickness insurance for the farm worker—including the same maternity benefits as for industrial workers—and the applicability of the Works Council law to agriculture. Needless to say, it proved very difficult to enforce a good deal of the labor legislation in many areas so that considerable differences in the degree of observance of agricultural labor laws prevailed among the various regions of the Reich. These strengthened the high degree of differentiation in the institutional arrangements of agriculture that existed, for reasons of history, climate, soil, etc., in different areas. Trade unions of agricultural workers which had been set up after 1908 played a not unimportant role in the efforts for the improvement of the lot of agricultural labor, even though the tremendous membership gains made at the end of the Second World War could not be maintained long.

After the Nazis came to power, the attempt to set up a market economy in agriculture was abandoned in favor of a rigidly controlled system designed to encourage the remigration of the city dwellers to the land. "The Third Reich will be a peasant Reich or it will not be at all." This romantic ideal soon came into conflict with other objectives of Nazi policy: self-sufficiency of food supplies and effective preparation for an armed conflict. The author demonstrates convincingly how the "blood and soil" dreams of the new government had to give way, gradually but decisively, to the requirements of a nation preparing for war. The size of the farming units increased, mechanization progressed—at the expense of peasant farming which the new government had set out to strengthen. In the long run, the Nazis made no impact upon the evolution of German agriculture. The institutions created by them perished without a trace when the regime collapsed.

The treatment is essentially historical and descriptive. Few attempts are made to generalize, or to use the body of economic theory. Within these limits, this is a first-rate study.

ADOLF STURMTHAL

University of Illinois

Labor in the United States. By SANFORD COHEN. Columbus: Charles E. Merrill Books, 1960. Pp. xii, 676.

The choice of a text on the U.S. labor movement often hinges on whether the stress is on historical and institutional criteria or economic theory. Authors use various means to emphasize one of these areas or to combine them. One noted text in the field uses the device "of a two-part treatment with cross linkages wherever possible." Another is described as "an amalgam of two books: one on unions and industrial relations and another on wages, income distribution and labor mobility, etc." For his part, Cohen believes that "the major deficiency of the U.S. undergraduate student of the social sciences is a lack of historical perspective, and that an overemphasis upon contemporary events and theories produces an ephemeral knowledge that evaporates as events move on and theories change." The result is that the economics of labor

constitutes about 30 per cent of this book in contrast to the 40 or 50 per cent found in most labor texts. On the other hand, labor history and labor law have been more fully elaborated.

Part I deals with the development from colonial times of a labor force concept, with coverage of occupational, industrial and some philosophical characteristics of U.S. labor. Parts II through V deal with the familiar history of U.S. labor; the issues in collective bargaining; wage analysis; and labor law, from the origins of the Conspiracy Doctrine to the Landrum Griffin Law. Part VI treats of social security and the unemployment problem. Part VII discusses whether radical, conservative, or liberal forces govern labor's role in U.S. society. Each chapter concludes with questions and a helpful selection of readings. Organized in this way, the book is adaptable to any emphasis required in a particular labor course or by an instructor's preference.

As a broad survey of labor in the United States, this is a sound text. Considering the scope of the material covered, it is inevitable that some parts are stronger than others. Some of the historical chapters seem sketchy, and causal factors behind important events and concepts are not as fully developed as one would wish. For example, slave labor, immigration policy, labor philosophy, the impact of early radicalism, the great 1919 steel strike, the ambivalent forces set adrift in the 1920's and 1930's, the locus of power in the AFL-CIO structure, union finances—all are among the aspects of the book which receive cursory treatment. In view of the growing list of right-to-work laws and, to quote the author, the "mountain of right-to-work literature," and considering the resurgent conservative voice in American life and politics, the discussion on this issue in this text, as in most others, is for some inexplicable reason sparse.

In another area, adequate treatment of the impact of recent immigration from Puerto Rico and other Caribbean areas is wanting. This is one type of worker that unionism, in its original pristine fervor and impetus, sought to help. With attention drawn to the power and prestige struggle, labor leaders may have lost touch with the "job consciousness" which has long attracted the allegiance of the daily wage dependent. While it is true that this immigration constitutes a problem primarily to New York, the failure of the union movement to protect the newly arrived laborer from the unscrupulous employer, and in fact from the complicity of some locals, may in a real sense be an indictment of the preoccupation and indifference of an oversophisticated leadership. Cohen has a brief discussion of the Puerto Rican workers, but does not implicate the union movement analytically or conceptually in this problem. Nor, for that matter, do any of the current labor texts.

On the other hand, Cohen's chapters on Collective Bargaining, Wage Determination, Labor Law, Social Security and Unemployment, and the general discussion on labor's role in U.S. society in the "Conclusion" provide the meaty core of the book. Chapter 14 on "Inflation and Wages" is excellent and especially timely.

When Cohen suggests that marginal analysis "provides few insights into the complexities of wage determination," due to the presence of so many other factors, he echoes the views found in other labor texts. The consequence is

that macro-marginalism finds expression here, while marginal wage determination in the firm is briefly treated. This omission deprives students of good mental discipline and of the kind of esoteric insights into wage issues not likely to be gained out of school.¹

Those who consider this book will be guided by their own predispositions concerning the old battle between theory and institutionalism as the better foundation for understanding labor's problems. Most would agree that the safest approach is to assume that they are equally important. The real task is to make students aware of the importance of issues which bear upon contemporary labor problems, so that they know what is significant for further study when the occasion demands. The argument on behalf of stressing theory is that the nontheory areas may well form the supplementary reading list, while a better than rudimentary grasp of the economics of labor requires some classroom guidance and help.

Instructors who feel this way, and who also believe that only bad theories change and only good ones are taught may not be attracted by this author's choice of emphasis. On the other hand, this text would be better than most for the broad survey course, or for the general reader in need of a good over-all grasp of the labor movement in the United States.

RICHARD J. WARD

Amman, Jordan

¹ The kind of elementary coverage of micro-marginal wage theory contemplated may be found commendably done, for example, in Stonier and Hague's *A Textbook of Economic Theory*, London 1957, Ch. 10-12. But K. Boulding's *Economic Analysis*, New York 1955, Ch. 28; R. Leftwich in *The Price System and Resource Allocation*, New York 1960, Ch. 13-15; or Daniel Hamburg's *Principles of a Growing Economy*, New York 1961, Ch. 30, also give typical, if more sophisticated, treatment of the kind of marginal wage analysis that is lacking in most labor texts.

- This is a successor to the author's *The Theory of Forward Exchange* (1937). In his preface to the present book, he writes that he has made some use of the prewar materials, but has added a great deal of new material: "The result is the present book. At least three-fifths of the material it contains is either entirely new or it has been thoroughly rewritten, in addition bringing it up to date. The remaining two-fifths, too, had to be revised more or less, reinterpreted and brought up to date, . . ."

NOTES

EDITORIAL NOTE

It is with great satisfaction that I announce that the Executive Committee of the Association has appointed John G. Gurley to succeed me as managing editor of the *Review* on January 1, 1963. The journal will be in highly competent hands.

Also, during my temporary absence in the months of April-June of the current year, Professor Gurley has kindly consented to serve as acting managing editor; and Professor Lorie Tarshis will be associate editor.

BERNARD F. HALEY

Theodore W. Schultz, department of economics, University of Chicago, has been appointed chairman of the American Economic Association nominating committee. Suggestions for officers of the Association in 1963 should be sent to him as early as possible.

THE AMERICAN ECONOMY—A TELEVISION COURSE

Learning Resources Institute (LRI) is planning a television course for college credit in "The American Economy." The course will be presented during the 1962-63 academic year over CBS Television Network. A number of educational television stations also will carry the series. LRI hopes that educational institutions and school systems will develop plans for utilizing the course as part of their regular curricula and inservice training programs.

The course is sponsored by The National Task Force on Economic Education, the American Economic Association, and the Joint Council on Economic Education. The Task Force (G. L. Bach, chairman) will act as an advisory committee.

Further information about the course can be obtained from Anne P. Folger, National Coordinator, Learning Resources Institute, 680 Fifth Avenue, New York 19, New York.

THE CENTER FOR QUANTITATIVE STUDY OF ECONOMIC STRUCTURE AND GROWTH

A Center for Quantitative Study of Economic Structure and Growth has been established at Yale University under a grant from The Ford Foundation. Its purpose is to further comparative analysis of the structure and development of national economies.

The research program emphasizes the search for regularities in the process of growth and structural change by means of intercountry and intertemporal studies. To provide more reliable statistical tests of theoretical hypotheses, the Center is concerned with improving the techniques of economic measurement and with refinement of national data systems. The Center maintains a library of relevant statistical and economic documents published by national governments and international organizations. It also operates a training program for economists and statisticians employed in foreign government agencies with a view to strengthening national planning and statistical organizations over the long run.

The Center has been planned as a research resource for scholars anywhere in the world who are working on problems within its area of interest. A number of visiting scholars from other institutions will be in residence each year.

The officers of the Center are Lloyd G. Reynolds, director; Gustav Ranis, associate director; and Mariam Chamberlain, executive secretary. A fuller description of The Center's interests and activities is available on request.

CENTER FOR RESEARCH ON ECONOMIC DEVELOPMENT

A Center for Research on Economic Development (CRED) has been established at the University of Michigan for the study of economic development and national and international programs designed to accelerate such development in underdeveloped countries.

The Center's research is theoretically oriented and primarily directed to increasing scientific understanding of economic growth and development in the less developed countries. It is concerned with noneconomic as well as economic conditions and draws upon the data, concepts and methods of a variety of disciplines through the facilities of a university-wide organization. Instruction in the various disciplines and professions is given by the established department of the University and a doctoral program in development economics is offered in the department of economics. Samuel P. Hayes has been appointed director of the Center for a three-year term.

NATIONAL SCIENCE FOUNDATION PROGRAMS IN ECONOMICS

The National Science Foundation now includes in its fellowship and grant programs all of economics, econometrics, economic statistics, and economic and social geography, where previously only mathematical economics and econometrics were included. The following programs will be of interest to economists:

1. *Grants for Scientific Research*: Closing filing dates are February 1, May 1 and October 1, with notification of the Foundation's action approximately 3 months later.

2. *Postdoctoral Fellowships* (semi-annual awards): In support of scientists who have recently received a doctors' degree and who need or are qualified for additional advanced training. Stipend at an annual rate of \$4500 to \$5000 plus dependency allowance for periods from 6 months to 2 years. Application deadlines: early September and mid-December, awards in October and March.

3. *Senior Postdoctoral Fellowships* (annual awards): To senior scientists of demonstrated ability who have had the doctoral degree at least 5 years or who have had equivalent scientific training or research experience. Stipends are computed on fellow's income at time of application to a maximum of \$15,000 per annum, for periods from 3 months to 2 years. Application deadline: early October, awards in mid-December.

4. *Science Faculty Fellowships* (annual awards): Primarily for college teachers with a view towards enhancing their effectiveness as teachers. Applicants must have at least three years of college teaching experience, a baccalaureate degree, demonstrated ability and a special aptitude for teaching and advanced training. Stipends are computed on fellow's income at time of application to a maximum of \$15,000 per annum for periods of 3 months to 15 months. Application deadline: early October, awards in mid-December.

5. *Graduate (predoctoral) Fellowships* (annual awards): For students studying for doctor's degree. Applicants required to take examinations testing scientific aptitude and scholarship achievement. Stipend from \$1800 to \$2200 for a maximum of one regular academic year plus a full summer session. Dependents' allowances are provided for, as well as a limited allowance for travel to the student's institution. Application deadline: early January, awards in mid-March.

6. *Cooperative Graduate Fellowships* (annual awards): Application is through the participating institution he expects to attend as a fellow. Stipend at an annual rate of \$2200 for either 9 or 12 months.

7. *Summer Fellowships for Graduate Teaching Assistants* (annual awards): Application is through the participating institution. Provides support to selected graduate teaching assistants to enable them to devote full-time to scientific research or study during the summer months. Stipend \$50 to \$75 per week with tenure of 8 to 10 weeks.

8. *Undergraduate Science Education Program*: Economics Departments may apply on behalf of undergraduates in economics for support of programs to promote research participation and independent study by able undergraduates. For summer participants, a stipend not to exceed \$60 per week or \$600 for the whole summer may be provided for full-time participation for a period of not less than 8 weeks. For academic-year programs, an average stipend of \$150 per participant for part-time participation requiring from 8 to 10 hours per week of the student's time is provided for, with a maximum per participant of \$300 for the academic year. Proposals may be submitted September 15, January 15, and June 15 respectively.

9. *Undergraduate Scientific Equipment Program*: Equipment grants designed to assist in the purchase of scientific equipment for undergraduate instruction. This program does

not encompass economics in general, but does include statistics. A maximum per proposal of \$25,000 is provided for, with a requirement of a matching contribution by the recipient institution from nonfederal sources of at least 50 per cent of the direct cost.

Inquiries concerning fellowship programs and undergraduate equipment should be addressed to Division of Scientific Personnel and Education, National Science Foundation, Washington, D.C.

THE EDWIN FRANCIS GAY MEMORIAL PRIZE IN ECONOMIC HISTORY

The Economic History Association announces a biennial prize competition for the best unpublished manuscript in the general field of economic history. The award, called the Edwin Francis Gay Memorial Prize in Economic History, will be \$1,500.00 plus payment of costs required to assure publication of the prize-winning manuscript. Funds for the prize will be contributed by the Council on Research in Economic History.

Preference will be given to manuscripts which combine breadth of enquiry and insight; which open up new areas of scholarship; which explore analytically major changes or developments in economic processes or institutions. No award will be made if, in the opinion of the judges, no manuscript is of acceptable quality.

The competition is open to any U.S. or Canadian scholar. Manuscripts must be in English and should not exceed the equivalent of 350 printed pages. Two copies should be submitted. The manuscript should contain no internal evidence of authorship, but should be accompanied by a signed letter.

Manuscripts should be sent to Ralph W. Hidy, Secretary of the Economic History Association, Morgan Hall, Graduate School of Business Administration, Harvard University, Boston 63, Massachusetts, before July 15, 1962.

Announcements

The Group for Afro-Asian Social Studies of the University of Cambridge has established a documentation center in the Faculty of Economics building. The center contains reports on economic, political and social questions and a bibliography arranged under regions and subjects. Research programs and interdisciplinary seminars are being organized and the Inter-Disciplinary Seminar on African Problems, which has been held in Cambridge the past two years, will be attached to the Centre. Inquiries about the Documentation Centre should be addressed to the Librarian, Miss Julia Allen, Afro-Asian Group, Faculty of Economics, Sidgwick Ave., Cambridge, England. Information about the Group's program may be addressed to Mr. Kenneth Berrill at the same address.

The City College, Hunter College and Brooklyn College of the City University of New York are offering an interdisciplinary program in Russian Area Studies which will lead to the degree of Master of Arts in Russian Area Studies. Courses are offered in Russian history and civilization, economics, literature, education, psychology, and political theory and practice. Inquiries may be sent to the Graduate Divisions of the participating colleges.

The Harvard Graduate School of Business Administration announces the availability of funds to aid archivists, librarians, and researchers interested in investigating topics in economic and business history or in studying the acquisition and handling of archival material, manuscripts, and books in this field. The School's unique resources in these areas will be available to such persons during the summer of 1962. Members of the Business History Group and the staff of Baker Library will be available for consultation and guidance, but applicants who receive assistance will be free to pursue their projects as they think best. The criterion for awarding financial aid will be primarily the extent to which the use of the School's resources can be expected to advance proposed projects. Inquiries may be addressed to Ralph W. Hidy, Morgan 304, Harvard Graduate School of Business Administration, Soldiers Field, Boston 63, Massachusetts.

Harvard University announces a new program of research fellowships in Forest Resources. These fellowships carry stipends up to \$15,000, the amount of each award depending on the professional status and needs of the recipient. Proposed research on scientific, economic, political, administrative, and legal aspects of forestry and forest management comes within the scope of the program. Address the Committee on the Charles Bullard Fund for Forest Research, Littauer Center 123, Harvard University, Cambridge 38, Mass.

Under the name, Colegio Nacional de Economistas de Cuba (en el Exilio), an organization of Cuban economists in exile has been formed with its headquarters in Miami, Florida. The founding members had been members of the Colegio Nacional de Economistas de Cuba which was constituted in Cuba in 1956. Dean of the new organization is Professor Luis J. Abalo; and the address is P.O. Box 35-416, Miami, Florida.

In cooperation with the Agency for International Development, Michigan State University is helping develop the University of Nigeria which was established in 1960 at Na ukka, Nigeria. The University, which now has a student body of 1,000 and a staff of 100, is in urgent need of books in agriculture, business administration, economics, finance, and in fact most fields. Books may be sent to: Dr. George H. Axinn, Coordinator, University of Nigeria Program, A-4 Wells Hall, Michigan State University, East Lansing, Michigan.

Deaths

G. E. Britnell, professor and head, department of economics and political science, University of Saskatchewan, October 14, 1961.

Frederick S. Deibler, professor emeritus, Northwestern University; secretary-treasurer, American Economic Association, 1926-35; December 26, 1961.

James L. Dohr, emeritus professor of accounting, Columbia University Graduate School of Business, November 24, 1961.

Luigi Einaudi, first president of Italy; honorary member of the American Economic Association; October 30, 1961.

A. Anton Friedrich, New York University, April 1961.

James K. Hall, University of Washington, January 5, 1962.

Orville Hall, College of Business Administration, University of Arkansas, September 27, 1961.

John J. Long, Fryeburg, Maine.

Clarke D. Pease, Fairview, Tennessee, September 4, 1961.

Harry Sherr, U.S. Department of Agriculture, December 9, 1961.

Paul Studenski, professor emeritus of economics, School of Commerce, Accounts, and Finance, New York University, November 2, 1961.

Ray B. Westerfield, emeritus professor of economics, Yale University; secretary-treasurer, American Economic Association, 1921-22, vice-president 1925; September 12, 1961.

Leo Wolman, emeritus professor of economics, Columbia University; National Bureau of Economic Research; October 2, 1961.

Retirements

E. Clair Bancroft, Colgate University, February 1961.

E. T. Bullock, University of Miami School of Business Administration, June 1962.

C. K. Ganong, Purdue University, June 1962.

M. Slade Kendrick, Cornell University, June 1962.

Victor P. Morris, dean emeritus, University of Oregon, December 1962.

Vera K. Russell, director, Bureau of Business Research, New York State Department of Commerce, November 1961.

Visiting Foreign Scholars

Ljubisa Adamovic, Institute for International Politics and Economy, Belgrade, Yugoslavia: visiting lecturer in economics, Florida State University, spring semester, 1962.

John Jewkes, Oxford University, Oxford, England: visiting professor Princeton University, fall term 1961-62.

Jean St. George Kerr, University of Melbourne: visiting lecturer in accounting, Columbia University, Graduate School of Business, spring term, 1962.

Alexander Lamfalussy, Director of Economic Research, Banque de Bruxelles: visiting lecturer in economics, Yale University.

Peter Mathias, Queen's College, Cambridge, England: visiting lecturer in economics, department of political economy, University of Toronto.

Dudley G. Seers, Economic Commission for Latin America, Santiago, Chile: visiting professor of economics, Yale University.

Jan Tinbergen, Netherlands School of Economics, Rotterdam: Philips Visitor, Haverford College, April 1962.

Janusz G. Zielinski, The Central School of Planning and Statistics, Warsaw, Poland: visiting lecturer in economics, Yale University.

Promotions

Victor L. Andrews: assistant professor, Graduate School of Business Administration, Harvard University.

Philip W. Bell: professor of economics, Haverford College.

Maurice C. Benewitz: associate professor of economics, The City College of New York.

Marion A. Buck: associate professor of business administration, College of Business Administration, Syracuse University.

Elwood Buffa, professor of production management, School of Business Administration, University of California, Los Angeles.

Joseph Carrabino: professor of production management, School of Business Administration, University of California, Los Angeles.

Charles J. Christenson: assistant professor, Graduate School of Business Administration, Harvard University.

Alfred H. Conrad: associate professor, Graduate School of Business Administration, Harvard University.

Stanley L. Dolins: assistant professor of economics, United States Air Force Academy.

M. Mason Gaffney: professor of agricultural economics, University of Missouri.

John I. Griffin: professor of economics, The City College of New York.

Neil E. Harlan: professor, Graduate School of Business Administration, Harvard University.

Leon E. Hay: professor of accounting, School of Business, Indiana University.

Donald D. Hester: assistant professor of economics, Yale University.

Arthur M. Johnson: associate professor, Graduate School of Business Administration, Harvard University.

Douglas N. Jones: assistant professor of economics, United States Air Force Academy.

Gordon M. Kaufman: assistant professor, Graduate School of Business Administration, Harvard University.

William N. Kinnard, Jr.: professor of finance and real estate, University of Connecticut.

Philip A. Klein: associate professor of economics, The Pennsylvania State University, University Park, Pennsylvania.

Marvin E. Lee: assistant professor of economics, Hofstra College.

Ch'ung-tai Lu: associate professor of economics, Baldwin-Wallace College.

Bevars D. Mabry: associate professor of economics, College of Business Administration, Bowling Green State University.

E. W. Martin, Jr.: professor of business administration, School of Business, Indiana University.

David Moment: assistant professor, Graduate School of Business Administration, Harvard University.

Monroe Newman: professor of economics, The Pennsylvania State University.

Robert L. Peterson: assistant professor, Graduate School of Business Administration, Harvard University.

J. Richard Powell: professor, department of economics, Long Beach State College.

Gustav Ranis: associate professor, department of economics, Yale University.

Robert Scharf: professor of social sciences, Georgia Institute of Technology.

Harry Simons: professor of accounting, School of Business Administration, University of California, Los Angeles.

J. Douglas Snider: associate professor of management, School of Business, Indiana University.

Thirukodikaval N. Srinivasan: assistant professor of economics, Yale University.

Robert C. Turner: distinguished service professor, School of Business, Indiana University.

Robert F. Vandell: associate professor, Graduate School of Business Administration, Harvard University.

Immanuel Wexler: assistant professor of economics, University of Connecticut.

Administrative Appointments

Henry S. Ang: assistant professor of economics and chairman of the department, Tougaloo Southern Christian College.

Walter D. Barndt: administrative director of the advanced management program, Graduate School of Business Administration, Harvard University.

Norman N. Bowsher: assistant vice president, Federal Reserve Bank of St. Louis.

Alpha C. Chiang: chairman, department of economics, Denison University.

Meredith Givens: senior research staff, and executive officer for international program, Institute of Public Administration, New York.

William I. Greenwald: acting chairman, department of economics, The City College of New York.

Samuel P. Hayes: director, Center for Research on Economic Development, University of Michigan.

John E. Jeuck: acting associate dean, Graduate School of Business, University of Chicago.

Alex J. Kondonassis: chairman, department of economics, University of Oklahoma.

Robert F. Lanzillotti: head, department of economics, Michigan State University.

John P. Lewis: chairman, department of business economics and public policy, Indiana University.

James S. Lipscomb: associate director of overseas relations, Graduate School of Business Administration, Harvard University.

Norman Locksley: U. S. Army, program coordinator, Allied Forces Southern Europe, Naples, Italy.

James H. Lorie: director of research, Graduate School of Business, University of Chicago.

Howe Martyn: professor of international business and assistant director, international business program, School of Business Administration, The American University.

James A. Morris: dean, School of Business Administration, University of South Carolina.

Garland C. Owens: associate dean, Columbia University Graduate School of Business.

E. Bryant Phillips: chairman, department of economics, University of Southern California.

W. George Pinnell: acting chairman, department of finance, School of Business, Indiana University.

Lawrence S. Ritter: chairman, finance department, Graduate School of Business Administration, New York University.

Richard H. Slavin: chairman, department of economics, Bethany College.

Anthony M. Tang: acting director, graduate program in economic development, Vanderbilt University.

N. Arnold Tolles: Board of Directors, New York State Council on Economic Education.

Guy W. Trump: dean, School of Business Administration, Emory University.

Henry H. Villard: chairman, department of economics, The City College, New York.

Howard A. Ward: associate director, Institute for Business Services and associate professor of economics, University of Detroit.

Harold L. Wattel: chairman, division of business, Hofstra College.

Marshall D. Wattles: director, Honors College, University of Oregon.

Jack R. Wentworth: director of the Bureau of Business Research and assistant professor of business administration, School of Business, Indiana University.

Appointments

William Abraham: professor, Graduate School of Arts and Science, New York University.

Ralph L. Andreano: assistant professor, Harvard University Graduate School of Business Administration.

Gordon C. Armour: assistant professor of management, School of Business, Indiana University.

George D. Bailey: Regents professor of accounting, School of Business Administration, University of California at Los Angeles.

N. Robert Bartell: acting assistant professor of finance, School of Business Administration, University of California at Los Angeles.

Yoram Barzel, University of Chicago: assistant professor, University of Washington.

Walter P. Blass, R. B. Blass Company: economist, Chief Statistician's Division, A T & T Co.

Dwight M. Blood, Wyoming Legislative Council: fiscal economist, staff of the Office of Tax Analysis, Department of the Treasury.

Patrick M. Boarman, University of Wisconsin-Milwaukee: associate professor of economics, Bucknell University.

Ralph Bristol, RAND Corporation: fiscal economist, staff of the Office of Tax Analysis, Department of the Treasury.

James E. Brown: assistant professor, School of Business Administration, Emory University.

R. Gene Brown: assistant professor, Harvard University Graduate School of Business Administration.

Robert D. Buzzell: assistant professor, Harvard University Graduate School of Business Administration.

George Chacko: acting assistant professor of statistics, School of Business Administration, University of California at Los Angeles.

Edward L. Claiborn: instructor in economics, United States Air Force Academy.

James D. Clokey III: instructor in economics, Washington and Jefferson College.

Morris Cohen, The City College of New York: lecturer in economics, Graduate Division, College of Business Administration, St. John's University, New York.

Arnold C. Cooper: instructor in business administration, Harvard University Graduate School of Business Administration.

Jon S. Cunningham: instructor in economics and statistics, Graduate School of Business, University of Chicago.

Clarence H. Danhof, Tulane University: Brookings Institution.

Robert L. Dickens: professor, department of economics and business administration, Duke University.

Eldon J. Dvorak, University of Washington: assistant professor, department of economics, Long Beach State College.

Robert V. Eagly: assistant professor of economics, Wayne State University.

Edward C. Ettin: assistant professor, department of economics and business administration, Duke University.

George J. Feeney, General Electric Company: visiting professor of economics, Yale University.

Rachel Floersheim: lecturer, The City College of New York.

Kenneth U. Flood: visiting lecturer in business administration, Harvard University Graduate School of Business Administration.

Lawrence E. Fouraker: lecturer in business administration, Harvard University Graduate School of Business Administration.

Henry J. Frank: associate professor of economics, Fairleigh Dickinson University.

Lee E. Glick: assistant professor of economics, Washington and Jefferson College.

Amor Gosfield: lecturer, Wharton School, University of Pennsylvania.

Robert C. Goshay: acting assistant professor of finance, School of Business Administration, University of California at Los Angeles.

Michael A. Hall: lecturer in economics, Hunter College.

Michel D. A. Hervé, Harvard University: assistant professor, department of economics, Long Beach State College.

Alan W. Heston: assistant professor of economics, Yale University.

James E. Hibdon, Texas A. & M.: associate professor of economics, University of Oklahoma.

William R. Hoskins: assistant professor of international business administration, School of Business, Indiana University.

Richard Hyse: assistant professor of economics, Oswego State College.

E. A. J. Johnson: visiting professor of economic history, School of Advanced International Studies, Johns Hopkins University.

Norman Kaplan: Xerox professor of international economics, department of economics, University of Rochester.

Harold H. Kassajian: acting assistant professor of marketing, School of Business Administration, University of California at Los Angeles.

William B. Kelly, Fletcher School of Law and Diplomacy: international economist, Department of State.

Marshall R. Kolin: assistant professor, Harvard University Graduate School of Business Administration.

John M. Kuhlman: associate professor of economics, University of Missouri.

Max E. Lupul: acting assistant professor of marketing, School of Business Administration, University of California at Los Angeles.

- Feng-hwa Mah, University of California: assistant professor, University of Washington.
- Edwin Mansfield: visiting associate professor of economics, Yale University.
- Hernan J. Mejia: instructor in economics, University of the Andes, Bogotá.
- Ryoichi Mikitani: assistant professor of money and banking, Kobe University of Commerce.
- Demetrius Moutsanides, University of Michigan: economist, Seattle-First National Bank.
- Richard A. Musgrave, Johns Hopkins University: professor of economics and public affairs, Princeton University.
- Lee C. Nehrt: assistant professor of international business administration, School of Business, Indiana University.
- E. William Noland: Ford Foundation visiting professor of business administration, School of Business, Indiana University.
- Benjamin Okner, Survey Research Center, University of Michigan: fiscal economist, staff, Office of Tax Analysis, Department of the Treasury.
- Mancur L. Olson: instructor in economics, United States Air Force Academy.
- Gerald Owens, U.S. Census Bureau: U.S. Department of Agriculture, Ohio State University.
- William G. Panschar: associate professor of marketing, School of Business, Indiana University.
- James A. Papke, Wayne State University: associate professor of economics, department of economics, School of Industrial Management, Purdue University.
- Charles A. Partin: assistant professor, department of business administration and economics, New Mexico State University.
- Mr. Gerald A. Pinsky, New York University: instructor, Washington Square College.
- John W. Pratt: associate professor, Harvard University Graduate School of Business Administration.
- G. David Quirin: assistant professor of finance, University of British Columbia.
- Ruth Rasch, Johns Hopkins University: fiscal economist, staff, Office of Tax Analysis, Department of the Treasury.
- Myron H. Ross: associate professor, department of economics, Western Michigan University.
- Richard Rowan: lecturer in industry, Wharton School, University of Pennsylvania.
- Peter Schran: assistant professor of economics, Yale University.
- Harry S. Schwartz, Federal Reserve Bank of San Francisco: advisor to the Federal Home Loan Bank Board, San Francisco.
- Joseph N. Seward, San Francisco State College: assistant professor, department of economics, Long Beach State College.
- W. Geoffrey Shepherd: instructor in economics, Yale University.
- William O. Shropshire: assistant professor, School of Business Administration, Emory University.
- Nelson L. Smith: visiting professor of business, Columbia University Graduate School of Business, 1962.
- Donald R. Snodgrass: instructor in economics, Yale University.
- Alan A. Spera: assistant professor of economics, The City College, New York.
- Koji Taira, Stanford University: assistant professor, University of Washington.
- Gordon Tullock: associate professor of economics, University of Virginia.
- Daniel H. Wagner: lecturer, Wharton School, University of Pennsylvania.
- Gerald O. Wentworth: visiting associate professor, Harvard University Graduate School of Business Administration.

Andrew B. Whinston: lecturer, departments of economics and industrial administration, Yale University.

Murray Yanowitch: assistant professor of economics, Hofstra College.

June M. Zaccane: instructor in economics, Hofstra College.

Leaves for Special Appointments

Bela Balassa, Yale University: assistant professor of economics, University of California, Berkeley, 1961-62.

Roger L. Bowlby, Michigan State University: consultant, Michigan Employment Security Commission, 1961-62.

Harry G. Brainard, Michigan State University: visiting professor, University of Arizona, Spring 1962.

Harvey E. Brazer, University of Michigan: director, Tax Analysis, U.S. Treasury Department.

Richard E. Caves, University of California, Berkeley: special assignment at the White House, Washington, D.C., September-December 1961.

Frank C. Child, Michigan State University: visiting associate professor, Stanford University, 1961-62.

R. Kirby Davidson, Purdue University: economic advisor to the social sciences division, Rockefeller Foundation, February 1962 for one year.

Dan H. Fenn, Jr., Harvard University Graduate School of Business Administration: staff of the President of the United States.

Lincoln Gordon, Harvard University Graduate School of Business Administration: U.S. Ambassador to Brazil.

J. Richard Huber, University of Washington: director, Economic Advisory Mission to Government of Afghanistan.

Thomas Mayer, Michigan State University: visiting associate professor, University of California, Berkeley, 1961-62.

Arthur M. Okun, Yale University: Council of Economic Advisors, Washington, D.C., 1961-62.

W. A. Paton, University of Michigan: visiting professor of accounting, University of Florida, second semester, 1961.

Hugh T. Patrick, Yale University: Ford Foundation sponsored program, to teach at the University of Bombay, 1961-62.

Merton J. Peck, Harvard University Graduate School of Business Administration: with the Comptroller of the Department of Defense, Washington.

Warren L. Smith, University of Michigan: staff, President's Council of Economic Advisers, 1962-63.

Jacob A. Stockfish, School of Business Administration, University of California at Los Angeles: Comptroller's Office, Pentagon, Fall 1961-Spring 1962.

Milton C. Taylor, Michigan State University: tax consultant to Pan American Union with special assignment in Honduras, Fall 1961.

James Tobin, Yale University: President's Council of Economic Advisers, 1961-62.

Lloyd Ulman, University of California, Berkeley: senior labor economist, Council of Economic Advisers, 1961-62.

Raymond Vernon, Harvard University Graduate School of Business Administration: consultant to the Undersecretary of State for Economic Affairs.

Henry H. Villard, The City College of New York: director, Economics Division, Ford Foundation, February-July, 1962.

Jay Wiley, Purdue University: economic advisor to the Undersecretary of State for Economic Affairs.

Resignations

Evan B. Alderfer, Wharton School, University of Pennsylvania, June 1961.

Frank S. Deming, Wharton School, University of Pennsylvania, June 1961.

Randolph S. Driver, Wharton School, University of Pennsylvania, June 1961.

James M. Fremgen, School of Business, Indiana University.

Robert Frye, School of Business Administration, University of California at Los Angeles, June 1961.

Philip Neff, School of Business Administration, University of California at Los Angeles, Fall 1961.

Roger Ulvestad, School of Business Administration, University of California at Los Angeles, June 1961.

Herbert S. Unterberger, Wharton School, University of Pennsylvania, June 1961.

Maneck S. Wadia, School of Business, Indiana University.

C. Arthur Williams, Wharton School, University of Pennsylvania, June 1961.

J. Peter Williamson, Harvard University Graduate School of Business Administration.

Miscellaneous

•Walter Adams, Michigan State University, appointed member of U.S. Advisory Commission on Educational Exchange.

John P. Henderson, Michigan State University, appointed consultant, Administration, Wage & Hour & Public Contracts Division, U.S. Department of Labor, 1961-62.

Robert S. Herman, director of research and fiscal policy, State of New York, division of the budget, has recently returned from a three month United Nations mission as an adviser to the government of Greece.

Clifford Hildreth, Michigan State University, appointed editor, *Journal of the American Statistical Association*.

VACANCIES AND APPLICATIONS

The Association is glad to render service to applicants who wish to make known their availability for positions in the field of economics and to administrative officers of colleges and universities and to others who are seeking to fill vacancies.

The officers of the Association take no responsibility for making a selection among the applicants or following up the results. The Secretary's Office will merely afford a central point for clearing inquiries; and the *Review* will publish in this section brief description of vacancies announced and of applications submitted (with necessary editorial changes). Since the Association has no other way of knowing whether or not this section is performing a real service, the Secretary would appreciate receiving notification of appointments made as a result of these announcements. It is optional with those submitting such announcements to publish name and address or to use a key number. Deadlines for the four issues of the *Review* are February 1, May 1, August 1, and November 1.

- Communications should be addressed to: The Secretary, American Economic Association, Northwestern University, Evanston, Illinois.

Vacancies

Labor economists: Department of Labor has openings for work in the fields of wages, manpower, employment, labor and industrial labor conditions and related fields. Salaries range from \$6,435 to \$13,730 depending upon experience and training. To apply, send résumé or Standard Form 57 to the Executive Secretary, Board of U.S. Civil Service Examiners, U.S. Department of Labor, Washington 25, D.C.

Economics and statistics: The Federal Trade Commission has vacancies for a limited number of economists. Candidates should have thorough academic training in economics and statistics. Preference will be given to candidates with training and research experience in the area of industrial organization. Some are for economists who conduct research in the area of industrial organization and behavior. Others are for economists providing economic assistance in the legal case work of the Commission. Vacancies exist for persons qualifying for Civil Service grades ranging from GS-9 to GS-14. Beginning grades and salaries vary, depending on experience and training. Qualified candidates with Ph.D.'s but without experience may receive a beginning grade of GS-12, which has a salary range of \$8,955 to \$10,255. Vacancies exist up to the GS-14 levels for persons with graduate training and with substantial research experience. The salary range for a GS-14 is \$12,210 to \$13,510. Write: Willard F. Mueller, Director of the Bureau of Economics, Federal Trade Commission, Washington 25, D.C.

Industrial organization, trade regulation, industrial concentration, structure of industry, price behavior: The Antitrust Division of the U.S. Department of Justice has openings for economists in Washington, D.C. Candidates should possess a background of education or experience in above fields. Duties involve the application of economic analysis to the enforcement of the antitrust laws. All positions are within the competitive civil service; entrance salaries range from \$5,355 to \$10,635 per annum. Write: Mr. John W. Adler, Chief, Personnel Office, Department of Justice, Washington 25, D.C.

Accounting: A small collegiate school of business in a metropolitan area in New England has a faculty opening in Accounting Department starting fall of 1962. Prefer applicants under 35 with Ph.D. or substantial completion of work toward Ph.D. Full-time position; rank of instructor or assistant professor; no previous teaching experience necessary; salary open; nine-month school year. P245

Agricultural economist: Production economics research; rank and salary determined by education and research but range of \$8,500-\$11,000 possible. Short-term applicants unwanted. Supply information required in Federal Form No. 57. Interested parties

apply Director, Land Study Bureau, University of Hawaii, Honolulu 14, Hawaii.

Economist: Ph.D. qualified in intermediate theory and national income. Must also be willing to teach principles. Classes under 40. Excellent retirement and disability program. Salary \$7,200 and up for nine months. Permanent, beginning September, 1962. Send application to Dr. H. F. Heller, Vice-President, Eastern Illinois University, Charleston, Illinois.

Business economics, finance, marketing, business organization: Catholic college in eastern Canada has opening for a man with advanced degree in business administration. Teaching and business experience preferred. Rank (lecturer or assistant professor) and salary according to qualifications and experience. Appointment tenable from September 1, 1962. Please submit complete résumé including salary. Write to Francis J. Hayes, Chairman of Economics Department, Loyola College, Montreal, Canada.

Economics: Instructor or assistant professor, to teach beginning course in statistics, but with preparation in beginning and advanced economics, with at least a master's degree. Some teaching or business experience preferred but not determining factor. Teaching load 12 to 15 hours; salary from \$5,000-\$6,800 for academic year, depending on degree and experience. T.I.A.A., sabbatical leaves, free tuition for faculty children available. Lutheran Church supported coeducational liberal arts college, 800 students. Write to Dean Wilhelm Reuning, Susquehanna University, Selinsgrove, Pennsylvania.

Technical assistant: For its program of technical assistant to the developing countries, the I.L.O. is looking for experts in the formulation and implementation of employment objectives in economic development to be assigned by the I.L.O. to serve as a member either (1) of the staff of a regional economic development institute to be set up in Latin America and later to be set up in Asia and Africa; or (2) of a group of experts advising a government on economic development planning and programming; or a combination of these functions. For details write to the Washington Branch Office, International Labor Office, 917 15th Street, N.W., Washington 5, D.C.

Marketing and applied economics: Presbyterian-related liberal arts college invites applications for appointment of assistant professor. M.A. required; Ph.D. preferred. Salary \$5,000 to \$7,000. Courses to be taught in marketing and allied subjects in economics. Write Ralph M. Sayre, Dean of the College, College of Idaho, Caldwell, Idaho.

Accounting: University of Nevada has a vacancy for an assistant professor to teach courses in elementary and intermediate accounting. C.P.A., M.A. or Ph.D. required. Applications should be sent to Andre Simmons, Chairman, Division of Business Administration and Economics, University of Nevada, Southern Regional Division, Las Vegas, Nevada.

Economics: Assistant professor in economics. New England state college, about 3,700 students. B.A., B.S., and M.A. degrees. Beginning salary \$7,280 for ten months with additional compensation for six weeks summer session. Begin September, 1962.

P250

Business finance: Finance department in accredited college and graduate school of business administration in relatively large eastern city needs a man to teach commercial financing; strength should lie in functional aspects of business finance, credits, analysis of statements, and commercial-bank lending operations, with auxiliary interests in an area such as investments, insurance, or mortgage banking. Doctorate or completion of course work with dissertation in progress desired; M.B.A. and/or LL.B. background preferred. Combination of 12-hour load, good teaching schedule, and minimum of other duties permits long periods of uninterrupted time for research and writing. Large banks and national corporate headquarters located nearby. Rank of associate professor and salary of \$8,500 for eleven months if qualifications suitable. Starting date September, 1962.

P251

Economics: Midwestern municipal university has full-time opening for an instructor; must be Ph.D. or near; expected to teach introductory courses plus some advanced undergraduate courses; labor economics background preferred but not essential; specialization and research not as important as good teaching ability; salary, with Ph.D., \$6,000 to \$6,900, depending on background; starting September, 1962.

P252

Transportation economist: American foundation offers short-term assignment for senior economist with broad experience in transportation field, to serve as a consultant in India for a period of six months. Position requires ability to do research on problem of economic and functional co-ordination of surface and air transport facilities and to assess their development potentials. Consultant will be paid fee corresponding to present salary, incentive bonus, and expenses. P253

Economist: American foundation offers short-term assignment for senior economist with experience in regional development programs in underdeveloped areas to serve as a consultant in India for a period of six months. Position requires ability to analyze pattern of regional development, make long-range projections and evaluate current programs to achieve a balanced growth and development of regional areas. Consultant will be paid fee corresponding to present salary, incentive bonus, and expenses. P254

Economics and business administration: Liberal arts college of 700 students in mid-west, opening as head of department of economics and business administration. Ph.D. in economics and some teaching experience required. Salary \$7,500 to \$11,000 for nine months, depending on qualifications. P255

Principles of economics and accounting: State college in Wisconsin. Prefer Ph.D. or near Ph.D. Salary \$6,500 to \$8,200. P256

Economists Available for Positions

Economic planning, research studies: Man; B.S. Economics, B.S. Foreign Trade, M.A. Business. Eleven years of experience in all phases of comptroller; presently a research analyst with a university. Will relocate. Salary open. E990

Labor economics, labor legislation, collective bargaining, labor market, principles, history of economic thought: Man, 40; Ph.D. Twelve years of college teaching experience; government positions; two books and numerous articles and reviews. E1001

The Econometric Society is an international society for the advancement of economic theory in its relation to statistics and mathematics.

Subscriptions to *Econometrica* and inquiries about the work of the Society and the procedure in applying for membership should be addressed to Richard Rugles, Secretary, The Econometric Society, Yale University, Box 1264, New Haven, Connecticut, U.S.A.

3 VITAL STEPS

bring you the world's best telephone service

1 • RESEARCH

The telephone was born of research and grows ever more useful the same way. Bell Telephone Laboratories conducts a far-reaching program for research and development—most of it in communications, but much of it defense.

Basic Bell inventions such as the Transistor and the Solar Battery have benefited man in many ways. And constant development of new equipment is revolutionizing telephony. But research alone doesn't bring service improvements and economies.

2 • MANUFACTURE

Research-created equipment must be manufactured to high standards at low cost, and made readily available anywhere in the nation.

That's Western Electric's job. Working closely with Bell Laboratories, Western Electric makes the vast amounts of high-quality equipment required for the telephone network. But the task still remains of putting this research and equipment to work—so they can make daily living easier and more pleasant for you and your family.

3 • OPERATION

Here, twenty-one Bell Telephone Companies step in. They take the results of Bell Laboratories research and Western Electric production and bring them to useful life on your bedside table or kitchen wall or office desk.

Research, manufacture and operation are interdependent and indispensable. Working as a team toward a common goal, they explain why this country has the world's finest telephone service and more telephones than all other countries combined!

Owned by more than two million Americans

DIXON-YATES

A Study in Power Politics

Aaron Wildavsky

One of the most widely debated political controversies in recent years, the Dixon-Yates case offers a panoramic view of American politics under the Eisenhower Administration. From the extensive documentation on this case and from a hundred personal interviews, Mr. Wildavsky skillfully reconstructs the extraordinary sequence of events involving crucial issues of public policy: public versus private power and conflict of interest. Many fundamental issues relating to the functioning of the American political system are also involved: the executive decision-making process; coalition politics in a system of fragmented powers; the right of executive privilege to withhold information from Congress; and the role of the regulatory agencies.

CHANGES IN THE LOCATION OF MANUFACTURING IN THE UNITED STATES SINCE 1929

Victor R. Fuchs

Since 1929 there has been a significant shift in the location of manufacturing in the United States which has had and will continue to have a profound effect on the nation's economic, political, and social life. Basing his work largely on unpublished Census of Manufacturing data, the author presents a comprehensive description and analysis of these changes. Mr. Fuchs investigates the determinants of mobility of all manufacturing industries. The effects of industrial structure, natural resources, labor, and markets on growth are considered, as are the relations between mobility and such industry characteristics as growth and concentration.

PROFESSIONAL MANAGEMENT

Theory and Practice

Theo Haimann

This new, skillfully written text offers tested concepts of management drawn from traditional management theories, tempered with the results of current thinking and recent research in the behavioral sciences. It utilizes the functions of a manager, namely planning, organizing, staffing, directing, and controlling, to make the basic principles of management understandable, relevant, and useful.

THE CONSUMER IN OUR ECONOMY

David Hamilton

Emphasizes consumer economics without neglecting important aspects of consumer education, thus allowing the instructor to stress abstract theory, practicality, or a combination of both. Applies the theory of consumer behavior to various aspects of consumption, and discusses it from the traditional indifference approach as well as from the newer behavioral approach.

MONEY AND ECONOMIC ACTIVITY

Readings in Money and Banking, Second Edition

Lawrence S. Ritter

An up-to-date selection of readings designed to stimulate student interest. Contrasting viewpoints are put in perspective by skillful editorial introductions, assuring a minimum loss of classroom time. Selections were chosen for their readability and current pertinence. New sections emphasize commercial banking, the money market, and the differential impact of monetary policy.

457 pages Paper covers 1961 \$4.50

MONEY AND BANKING

Leland J. Pritchard

A well-balanced presentation of practice and theory in the money and banking field, with emphasis on the basic aspects of bank administration as well as on the "economics" of money and banking. Includes tables, charts, and graphs closely integrated with the text; review questions at the conclusion of each chapter; and an extensive bibliography with cross-references. Instructor's Manual available.

783 pages 1958 \$7.25

MONEY, CREDIT, AND PUBLIC POLICY

Lawrence Smith

For money and banking courses, an integration of the subject matter of monetary economics with economics as a whole. Written with assurance, lucidity, and an occasional touch of humor, Professor Smith's distinguished text makes the subject of money and banking come alive for students. A brief bibliography concludes each chapter.

GARDINER MEANS

Pricing Power and the Public Interest

A Study Based
on Steel

The distinguished American economist here produces an original, creative approach to the pricing policies of the big corporation, in terms of a pioneer analysis of the steel industry and its actual cost and profit margins. Demonstrating that the traditional theory of price regulation by competition is no longer effective, he shows why neither government control nor fragmentation would be in the public interest. Instead, he proposes a new way to achieve a return on investment, consistent with corporate capital growth, that serves the whole economy. "A landmark book in its field."—*The Kiplinger Washington Editors*. 17 charts and 27 tables.

HARPER & BROTHERS, N.Y. 16

MURRAY N. ROTHBARD MAN, ECONOMY AND STATE

In this comprehensive and systematic treatise on economics, the author draws the conclusions logically implied in the fundamental axiom of human action. Written for students and laymen with no prior knowledge of economics as well as for the economist, its clear graphical representations of the major types of economic inter-relationships are an invaluable contribution to the two volume text.

Vol. I—leads step-by-step to an understanding of the structure of varied economies and an examination of the unhampered market. 496 pages

Vol. II—considers the problems of dynamic change and entrepreneurship in a free economy, presents a new theory of monopoly, and refutes the dominant economic fallacies of our age. 544 pages

the two volumes \$20.00

AGRICULTURAL HISTORY

Designed as a medium for the publication of research and documents pertaining to the history of agriculture in all its phases and as a clearing house for information of interest and value to workers in the field. Materials on the history of agriculture in all countries are included and also materials on institutions, organizations, and sciences which have been factors in agricultural development.

ISSUED QUARTERLY SINCE 1927

BY

THE AGRICULTURAL HISTORY SOCIETY

Subscriptions, including membership: Annual, \$5.00; student, \$2.00; contributing, \$10.00.

Editor: Fred W. Kohlmeyer, 3 Commerce Annex, University of Illinois, Urbana, Illinois.

Secretary-Treasurer: Wayne D. Rasmussen, Room 3446, South Agriculture Building, U. S. Economic Research Service, Washington, D.C.

INTERNATIONAL STUDIES

*Quarterly Journal of the Indian School of International Studies,
New Delhi*

International Studies contains articles in the fields of modern International Politics, Economics, and Law as well as on political, economic and social developments in Asia and other areas.

Vol. III

No. 2 (October 1961)

CONTENTS

West New Guinea: An Australian View	Norman Harper
The New Rouble and the Underdeveloped Countries	J. D. Sethi
Presidential System in the Republic of Viet-Nam	K. R. Bombwall
Alignment and Non-Alignment in Pakistan's Foreign Policy	B. O. Rastogi

Notes and Memoranda : Survey of Source Material : Bibliography

Annual Subscription: Rs.22: s.40: \$6.60

Single Copy: Rs. 6: s.11: \$1.80

3 MACMILLAN TEXTS COVER KEY AREAS OF MODERN ECONOMICS

MACROECONOMIC THEORY

By Gardner Ackley, University of Michigan

Professor Ackley's well-organized text offers a rigorous, detailed treatment of Keynesian and post-Keynesian macroeconomics, emphasizing their continuity with classical theories. There are full discussions of modern inflation theory; the growth models of Domar, Harrod, and Duesenberry; the dynamics of short-run movements and long-term growth; and the relevance of theory to policy.

1961, 597 pp., \$8.50

LABOR ECONOMICS AND INSTITUTIONS

By Arthur D. Butler, University of Buffalo

This up-to-date text analyzes unions and the labor force, collective bargaining, wages, unemployment and economic insecurity, and recent trends. All major labor legislation through the Landrum-Griffin Act is carefully evaluated. "A solid text for an introductory labor economics course. It is well-ordered, maintains interest without sacrificing analysis, and within a reasonable length it covers the material that most beginning labor courses are made of."—Earl F. Cheit, University of California (Berkeley), in *The American Economic Review*

1961, 595 pp., \$6.50

THE ECONOMICS OF PUBLIC FINANCE, Third Edition

By Philip E. Taylor, University of Connecticut

The latest edition of this authoritative text provides students with a thorough, working knowledge of the foundations and analytic techniques of public finance. It includes new material on fiscal measures to control inflation, fiscal policy for economic growth, strengthening the federal personal income tax, and the fiscal problems of state and local governments.

1961, 588 pp., \$7.50

**MONEY, BANKING,
AND PUBLIC POLICY**

by **HAROLD BARGER** • *Columbia University*

Carefully organized and well-written, this text treats fully all topics necessary for a firm foundation in understanding contemporary banking. The author's fresh approach includes such timely and important additions as discussion of banking in other countries and the monetary aspects of the business cycle. His classroom experience offers the student a more balanced, integrated and thought-provoking treatment of theory, description, and policy than any previous text.

FOUR OUTSTANDING FEATURES OF THIS NEW TEXT ARE:

1. A lucid description of bank and nonbank financial institutions, of the way they operate, and of policy problems connected with their regulation.
2. A compact, yet up-to-date and well-balanced account of monetary and fiscal theory. This account proceeds step by step with ample arithmetical and graphical illustrations, free from frills, and gives the student the basic understanding he needs for the discussion of policy problems.
3. A systematic discussion of the major policy issues of our time in a relevant historical setting. The potentialities of monetary and fiscal policy are appraised in relation to growth, unemployment, inflation and the gold problem.
4. A comprehensive treatment of contemporary banking with less emphasis on the extraneous details of banking history which plague the ordinary text.

HARRIS—FOURTH EDITION

THE AMERICAN ECONOMY

Principles, Practices, and Policies

By C. LOWELL HARRIS, Professor of Economics, Columbia University

The new Fourth Edition of this popular best text for the introductory course has been brought up to date and improved in many ways. As in earlier editions, it remains noteworthy for its rich and vital writing style, its high degree of professional competence in handling economic content, and its skillful blend of description, analysis, and theory. Again, it has been printed in two colors to increase the attractiveness of the format and to aid students in getting the most out of the charts and diagrams. A comprehensive Teacher's Manual will be available to adopters.

Davidson, Smith, and Wiley—REVISED EDITION

ECONOMICS

An Analytical Approach

By RALPH KIRBY DAVIDSON, VERNON L. SMITH, and JAY W. WILEY
all of Purdue University

This rigorous introduction to economic analysis provides the student with an analytical framework he can use both in understanding the operation of our economic system and in analyzing and making decisions at the individual firm level. It is especially useful for engineering, science, and mathematics students since it utilizes the mathematical training these students receive. The new Revised Edition has been brought up to date and improved in the light of classroom experience.

NUMBER THREE

MONETARY THEORY AND POLICY

By HARRY G. JOHNSON*

In order to isolate a field of study clearly enough demarcated to be usefully surveyed, it is necessary to define monetary theory as comprising theories concerning the influence of the quantity of money in the economic system, and monetary policy as policy employing the central bank's control of the supply of money as an instrument for achieving the objectives of general economic policy. In surveying the field thus narrowly defined fourteen years ago, Henry Villard [123] began by remarking on the relative decline in the significance attached to it as compared with the offshoot fields of business cycle and fiscal (income and employment) theory, a decline related to the experience of the 1930's, the intellectual impact of Keynes' *General Theory* [66], and the inhibiting effects of the wartime expansion of public debt on monetary policy. While this division of labor has continued, and has indeed been accentuated by the emergence of the cross-cutting field of economic growth and development as an area of specialization, the field of money has been increasingly active and has received increasing attention in the past fourteen years.

This recent activity in the money field can be explained in part by the general logic of scientific progress, according to which disputed issues are investigated with the aid of more powerful theoretical tools, and the implications of new approaches are explored in rigorous detail. Thus, in monetary theory, the issues raised by Keynes' attack on "classical" monetary theory have been worked over with the apparatus of general equilibrium analysis developed by J. R. Hicks [60] (to the gradual eclipse of the Robertsonian and Swedish period analysis once considered most promising), and Keynes' emphasis on treating money as an asset has been followed by subsequent theorists as a means of bringing money within the general framework of the

*The author is professor of economics at the University of Chicago. He is indebted to the University of Chicago Workshop in Money and Banking for discussions helpful in improving the presentation of the argument. [This is the fifth in a series of survey articles for which the Rockefeller Foundation has provided support.—*Editor.*]

theory of choice. In larger part, the revival of interest in money is a reflection of external developments—the postwar inflation, the consequent revival of monetary policy, and the persistence of inflation in the face of unemployment—together with recognition of the problems posed for both policy and theory by certain institutional characteristics of the modern economy (notably the widespread holding of liquid assets) and by potential conflicts between the diverse policy objectives now accepted as responsibilities of governmental policy.

The interest of professional economists in these matters has also been directly enlisted in the preparation of testimony and studies for a succession of large-scale enquiries into monetary policy and institutions, most recently the Radcliffe Report in Britain [127] and the Report [128] of the Commission on Money and Credit established by the Committee for Economic Development in the United States.¹ Finally, recent work on both theory and policy has been strongly influenced by the increased postwar emphasis on (and capacity for) econometric model-building and testing, and stimulated by the availability of new data—especially Raymond Goldsmith's data on saving [47] and financial intermediaries [48] in the United States, the Federal Reserve System's flow-of-funds accounts ([126] and subsequent publications), and Milton Friedman and Anna Schwartz' historical series of the United States money supply, forthcoming in [42].

While the impact of Keynes' *General Theory* has been so great that most of recent theory and research on money can be classified either as application and extension of Keynesian ideas or as counterrevolutionary attack on them, it seems preferable in a survey of the field to organize the material according to the main areas of research rather than according to the issues Keynes raised. Readers interested in the present status of Keynes' contributions to economics are referred to anniversary assessments by William Fellner and Dudley Dillard [32], James Schlesinger [102], H. G. Johnson [61], and R. E. Kuenne [71]. This survey deals with four broad topics: the neutrality of money; the theory of demand for money, which becomes the theory of velocity of circulation when the demand for money is related to income; the theory of money supply, monetary control, and monetary dynamics; and monetary policy. The theory of interest has been surveyed in a companion article by G. L. S. Shackle [105], and the theory of inflation is to be surveyed in a subsequent article in this *Review* by Martin Bronfenbrenner and Franklyn Holzman.

¹ For a list of Congressional documents bearing on monetary policy, see Friedman [34, pp. 103-40]; to Friedman's list should be added the *Staff Report on Employment, Growth and Price Levels* [129] and the accompanying *Staff Studies*.

I. *The Classical Dichotomy and the Neutrality of Money*

From the standpoint of pure theory, the most fundamental issue raised by Keynes in the *General Theory* lay in his attack on the traditional separation of monetary and value theory, the "classical dichotomy" as (following Don Patinkin [94]) it has come to be called, according to which relative prices are determined by the "real" forces of demand and supply and the absolute price level is determined by the quantity of money and its velocity of circulation. Keynes' attack has been followed by a protracted, often confused, and usually intensely mathematical investigation of the "consistency" or "validity" of the classical dichotomy, the requirements of a consistent theory of value in a monetary economy, and the conditions under which money will or will not be "neutral" (in the sense that a change in the quantity of money will not alter the real equilibrium of the system—relative prices and the interest rate). In the course of the controversy at least as much has been learned about the difficulty of extracting theoretical conclusions from systems of equations as has been contributed to usable monetary theory. The argument, it should be noted, has been concerned throughout with a monetary economy characterized by minimal uncertainty, whereas Keynes was concerned with a highly uncertain world in which money provides a major link between present and future (on this point see Shackle [105, p. 211]).

A. *The Integration of Monetary and Value Theory*

The early history of what is often described as "the Patinkin controversy" is not worth recounting in detail; an annotated bibliography of it may be found in Valavanis [122], and Patinkin's own summary in [90]. It began with Oskar Lange's argument [72] that Say's Law (which in this context is the principle that people sell goods only for the purpose of buying goods) logically precludes any monetary theory, since in combination with Walras' Law (that the total supply of goods and money to the market must be equal to the total demand for goods and money from the market) it implies that the excess demand for money on the market is identically zero regardless of the absolute price level, which therefore is indeterminate. Patinkin took up this charge, shifting the object of criticism to the classical assumption that the demand and supply functions for commodities are homogeneous of degree zero in commodity prices (that is, a doubling of all commodity prices will leave quantities demanded and supplied unchanged—in other words, quantities demanded depend only on relative prices). This criticism was refined and its mathematical formulation clarified in response to subsequent critical contributions, of which the most

important was Karl Brunner's demonstration [17] that a consistent monetary theory could be constructed without assigning utility to money.

In its final form at this stage [90], Patinkin's criticism of the classical dichotomy was that there was a logical contradiction between classical value theory, in which demands and supplies of commodities depended only on relative prices and not on the real value of people's cash balances, and the quantity theory of money, in which the dependence of spending on the real value of money balances provides the mechanism by which the quantity of money determines a stable equilibrium absolute price level, a contradiction which could be removed neither by resort to Say's Law nor by abandonment of the quantity theory in favor of some other monetary theory. But, Patinkin argued, the contradiction could be removed, and classical theory reconstituted, by making the demand and supply functions depend on real cash balances as well as relative prices; while this would eliminate the dichotomy, it would preserve the basic features of classical monetary theory, and particularly the invariance of the real equilibrium of the economy (relative prices and the rate of interest) with respect to changes in the quantity of money.

The integration of monetary and value theory through the explicit introduction of real balances as a determinant of behavior, and the reconstitution of classical monetary theory, is the main theme and contribution of Patinkin's monumentally scholarly work, *Money, Interest, and Prices* [93]. The first part of the book ("Microeconomics") develops the theory of the real balance effect (the effect of a change in the price level on the real value of money balances and hence on expenditure) in terms of a Hicksian exchange economy in which the individual starts each week with an endowment of commodities that must be consumed within the week and a stock of fiat money, and plans to exchange these for commodities to be consumed during the week and cash balances with which to start the next week. The demand for cash balances is a demand for real balances, derived rather artificially from the assumption that though equilibrium prices are fixed at the beginning of the week, cash payments and receipts are randomly distributed over the week and the individual attaches disutility to the prospect of being unable to pay cash on demand. A rise in prices lowers the real value of an individual's initial cash holding and, provided that neither goods nor real balances are "inferior," reduces his demand for both (implying a less than unit-elastic demand curve for money with respect to its purchasing power); but a proportional rise in prices accompanied by an equiproportional increase in the individual's initial money

of money [93, Ch. 12]: wage and price flexibility, inelastic expectations, absence of "money illusion," absence of "distribution effects," homogeneity of "bonds," and absence of government debt or open-market operations.⁴ This rarified set of assumptions is the main object of attack in J. G. Gurley and E. S. Shaw's *Money in a Theory of Finance* [52], a central purpose of which is to elucidate the conditions under which money will not be neutral.

Mention must first be made of an earlier, and influential, article by L. A. Metzler [83], whose analysis underlies the final assumption listed above. Metzler argued that the wealth-saving relationship assumed in the use of the Pigou effect by Keynes' critics to demonstrate that price flexibility would maintain full employment in the Keynesian model⁵ implied a theory in which changes in the quantity of money could affect the rate of interest (and consequently the rate of growth). Assuming for simplicity that government obligations are fixed in real terms, and that interest on government holdings of its own debt is returned as income to the community, Metzler showed that the price increase consequent on monetary expansion effected by open-market purchase of government debt would leave the community with a smaller stock of real assets and a greater willingness to save, thus lowering the equilibrium interest rate, though monetary expansion effected through the printing press would not alter the equilibrium interest rate. As Haberler shortly pointed out [54], Metzler's analysis of open-market operations implicitly rests on a distribution effect (the private sector but not the government being assumed to be influenced by a change in the latter's real debt); but subsequent writers, including Patinkin, have accepted this as a legitimate assumption, and Gurley and Shaw's analysis builds on it.

⁴ Absence of money illusion means that behavior depends on the real and not the money values of income, balances, and bonds; absence of distribution effects, that behavior is unaffected by redistributions of total real income, balances, and bonds among individuals, such as result from price-level changes; homogeneity of bonds, that behavior is affected only by the net creditor position of the private sector, not by the totals and composition of its assets and liabilities; absence of government debt or open market operations, that the net creditor position of the private sector consists in its holding of fiat money, or that, if government debt fixed in real terms is introduced (the Metzler case discussed below), its quantity does not alter when the quantity of money changes. The assumption of absence of distribution effects might seem unnecessary, on the Archibald-Lipsey argument, but that argument does not apply to this model, which by construction cannot be in full stationary equilibrium: see Ball and Bodkin's criticism of Archibald and Lipsey, which the latter accept [7, pp. 44-49].

⁵ The Pigou effect in modern usage is the effect on the demand for goods of a change in private real wealth resulting from the effect of a change in the price level on the real value of net private financial assets, the latter consisting of net government debt outstanding (including fiat money) and the part of the money supply backed by gold; it is the real balance effect corrected for the presence of government debt and money issued against private debt.

Gurley and Shaw's book is related to their earlier work on financial intermediaries in relation to economic growth and monetary policy; these aspects of their analysis will be taken up in the appropriate context. Their contribution to the neutrality discussion, apart from their insistence that rigidities, money illusion, expectations, and distribution effects may be quite important in actuality, consists in bringing back into the analysis the monetary and financial structure and the differing liquidity characteristics of different assets excluded by assumption in Patinkin's models. They begin by constructing a simple model alternative to Patinkin's, in which money is not itself government debt but is issued by the monetary authority against private debt ("inside" money, as contrasted with "outside" money), and showing that in this model the price level is determinate⁶ and money is neutral. They then show that money will not be neutral in a system containing inside and outside money, outside bonds, or a variety of securities against which money can be created. The key to these results is that in these cases an increase in the quantity of money of either variety, accompanied by a proportional increase in the prices of goods and private debts, alters the relative quantities of the various assets to be held by the public; and their significance to the neutrality debate can be reduced to any arbitrarily low level by arguing that they depend on a distribution effect, and that the appropriate test of neutrality is an equiproportional change in inside money, the assets backing it, and outside assets (see Patinkin [91, p. 108]). It may also be remarked that the results depend in no way on the presence of financial intermediaries.

Gurley and Shaw's analysis follows the tradition of Metzler and Patinkin in relating nonneutrality to the existence of government debt; their inside-money analysis merely makes noninterest-bearing as well as interest-bearing government debt a disturber of neutrality. This tradition leaves modern formal monetary theory rather awkwardly dependent on adventitious institutional or historical details; and the question naturally arises whether this is the best that can be done. The source of the difficulty lies in the implicit distribution effect introduced by the recognition that, unlike other debtors, the government does not have to worry about the size of its debts. For this difference there

⁶ Their insistence on the determinacy of the price level, in contrast to what they take to be the implication of Patinkin's approach (which they term "net money doctrine") [52, p. 76], rests on an understandable misunderstanding. Patinkin's analysis of price-level stability throws the emphasis on the wealth effect of a change in real balances resulting from a price-level change, an effect which only exists when money is a net asset; but it also provides for a substitution effect. Gurley and Shaw's demonstration that the substitution effect is sufficient to determine the price level therefore does not conflict with Patinkin's analysis (for Patinkin's views, see [91, pp. 100-09]), though it does show that Patinkin's emphasis on the wealth effect is misplaced and misleading. The broader implications of this point are discussed below.

are two reasons: (1) the government can always pay its debts by issuing fresh debts, since it controls the money supply, (2) the government can always command the resources required to pay the interest on its debts, since it possesses the taxing power. The latter is the reason relevant to the level of theoretical generality of the neutrality discussion; and at that level it provides grounds for denying that interest-bearing government debt should be treated as net assets of the public. The existence of government debt implies the levying of taxes to pay the interest on it, and in a world of reasonable certainty these taxes would be capitalized into liabilities equal in magnitude to the government debt; hence, if distribution effects between individuals are ignored, a change in the real amount of government debt will have no wealth-effect.⁷ Finally, if this logic applies to interest-bearing government debt, why should it not apply to the limiting case of noninterest-bearing government debt, which is equally a debt of the public to itself, and to commodity moneys, which are the same thing though based on custom rather than law?

This line of reasoning suggests that the more elegant approach to monetary theory lies along inside-money rather than outside-money lines, and that the foundation of the theory of monetary equilibrium and stability should be the substitution effect rather than the (in this case nonexistent) wealth effect of a change in real balances. It also has implications for the dichotomy debate: in the inside-money case the economy can be validly dichotomized into a real and a money sector, since the real-balance effect reduces to a change in the relative quantities of real balances and real debt (see Franco Modigliani [58, pp. 183-84] and Patinkin [91, p. 107]). Finally, it suggests an opportunity for a reassessment of Keynes' theory of employment, which is guiltless of the charges brought against it by Pigou and elaborated by Patinkin and others if interpreted as applying to an inside-money world.

II. *The Demand for Money and the Velocity of Circulation*

As Villard remarked in his earlier survey [123, pp. 316-24], the equation-of-exchange approach to monetary theory was eclipsed by the

⁷In an elegant recent article [86] R. A. Mundell has extended Metzler's analysis by considering explicitly the tax remissions resulting from open-market purchases of government debt. He assumes that corporate taxes are capitalized in the price of equities but that personal income taxes are not capitalized (there being no market for human capital); he allows for the effect of corporate taxation on the incentive to invest; and he demonstrates that Metzler's conclusion is valid if income taxes are remitted, but reversed if corporate taxes are remitted. The nonmarketability of human capital seems an inadequate reason for assuming that people do not feel richer when income taxes are reduced; consideration of the incentive effects of tax changes introduces an interesting new aspect of the neutrality problem but one that lies at a somewhat lower level of abstraction.

income-expenditure approach⁸ after 1930 largely because of the prevailing tendency to treat velocity as determined in principle by institutional factors governing the rapidity of circulation of the medium of exchange and as in practice a constant—a treatment clearly contradicted by experience in the 1930's. The alternative theory expounded by Keynes emphasized the determinants of expenditure; but it also contained a monetary theory founded on the function of money as a store of value and on the special characteristics of money as a form of holding wealth. This theory has been refined and elaborated by subsequent writers in the Keynesian tradition. In the process, Keynes' most extreme departure from previous analysis of the demand for money—his emphasis on the speculative demand for money at the expense of the precautionary—has been gradually abandoned (as has his awkward separation of the transactions and speculative demand for money), and the speculative motive has been relegated to the short run and reabsorbed into the general theory of asset holding. On the other side, the treatment of velocity as determined by payments institutions, while prominent in some expositions of the quantity theory, was by no means the core of classical monetary theory, which clearly recognized the opportunity cost of holding wealth in monetary form; and modern followers of the classical tradition, building on this foundation, treat velocity explicitly as reflecting a demand for money derived from preferences concerning the disposition of wealth.

In consequence, contemporary monetary theorists, whether avowedly "Keynesian" or "quantity," approach the demand for money in essentially the same way, as an application of the general theory of choice, though the former tend to formulate their analysis in terms of the demand for money as an asset alternative to other assets, and the latter, in terms of the demand for the services of money as a good. Aside from some conceptual perplexities concerning the relation between capital and income in this context, the chief substantive issues outstanding are three: first, what specific collection of assets corresponds most closely to the theoretical concept of money—an issue that arises as soon as the distinguishing characteristic of money ceases to be its function as a medium of exchange; second, what the variables are on which

⁸ These terms are intended to distinguish the two main (and historically long-established) schools of thought in monetary theory, one of which formulates its analysis in terms of the quantity of money and its velocity of circulation and the other in terms of the determinants of money expenditure, without ensnaring the exposition in the rights and wrongs of Keynes' protracted quarrel with what he understood by "the quantity theory." As this section explains, neither the quantity theory nor the Keynesian theory is now what it was in the 1930's; in particular, the modern quantity theorist is committed to neither full employment nor the constancy of velocity, and his theory is a theory of the relation between the stock of money and the level of money income, that is, a theory of velocity and not of prices and employment.

the demand for money so defined depends; and third, whether the demand for money is sufficiently stable to provide, in conjunction with the quantity of money, a better explanation of observed movements of money income and other aggregates than is provided by models built around income-expenditure relationships. These are essentially empirical issues, to which empirical research has as yet produced no conclusive answers; and they clearly have an important practical bearing on monetary policy.

A. Developments in Liquidity Preference Theory

To begin with the recent development of Keynesian analysis of the demand for money, subsequent contributions have been concerned with four aspects of Keynes' treatment of this subject: the separation of the demand into a transactions demand dependent on income and a liquidity-preference demand dependent on the rate of interest; the emphasis on the speculative element in liquidity preference; the neglect of wealth as a determinant of liquidity preference; and the aggregation of all assets other than money into bonds implicit in the use of a single (long-term) rate of interest.

The separation of the demand for money into two parts, besides being mathematically inelegant, incorporated the mechanical treatment of transactions demand that Keynes had criticized in the quantity theory. Keynesian writers (for example, Alvin Hansen [56, pp. 66-67]) began to treat transactions demand as reflecting economic behavior and particularly as being interest-elastic, from which it was a short step to making the demand for money as a whole depend on income and the rate of interest. The logic of treating transactions demand as reflecting rational choice was subsequently provided by W. J. Baumol [9] and James Tobin [117], the former's analysis being more interesting in that it links the problem to inventory theory. Both authors show that an economic unit starting a period with a transactions balance to be spent evenly over the period, and having the opportunity of investing idle funds at interest and withdrawing them as needed at a cost partly fixed per withdrawal, will disinvest at more frequent intervals (carry a lower average cash balance) the higher the rate of interest. They also show that the average cash balance held by the unit will be higher the higher the amount of the initial transactions balance, but less than proportionately higher.⁹

⁹ Ralph Turvey [121, p. 33], following Richard Selden [104, pp. 209-10], argues that the interest-elasticity conclusion does not extend to aggregate behavior because a change in the interest rate will have the opposite effect on the demand for cash of a unit facing a maturing debt and having the alternatives of holding cash in the interim or spending it and borrowing later. This argument involves an elementary confusion between saving behavior and asset management: savings effects of interest rate changes aside, the unit in

Keynes' emphasis on the extremely short-run speculative motive as the source of interest-elasticity in the liquidity demand for money was one of the main targets of Keynes' critics. Subsequent Keynesian writing has stressed Keynes' alternative explanation of liquidity preference, which rests this interest-elasticity on uncertainty about the future interest rate rather than on a definite expectation about its level; this explanation is really the precautionary motive in disguise (see Johnson [61, p. 8]). An elegant exposition of both explanations, using the theory of portfolio management, has been provided by Tobin [115].

The introduction of the value of wealth, which itself depends on the rate of interest, as an explicit determinant of the demand for money was part of a more general process of freeing Keynes' theory from its short-period equilibrium assumptions. It implied for the theory of liquidity preference, as noticed by Lloyd Metzler [83], Ralph Turvey [120] and Frank Brechling [10], that the liquidity-preference curve would be different for a change in the quantity of money brought about by fiscal policy than for a change effected by open-market operations (these two curves, and a third corresponding to constant wealth, are discussed in Turvey [121, Ch. 2]). It also introduces the difficulty, noted earlier by Borje Kragh [69], that the speculative demand curve for money traced out by open-market operations will differ according to the size of the units in which these are conducted, since the effects on wealth will differ. The wealth effects of discontinuity in open-market operations are exploited in Sidney Weintraub's recent contention [124, pp. 156-60] that the speculative demand curve is irreversible, as Richard Davis [30] has subsequently pointed out. At a far more fundamental level, the analysis of the demand for money that emerges from these developments, in which the demand for money depends on the interrelated variables income, the rate of interest, and wealth, raises important conceptual (and econometric) difficulties not always fully appreciated by monetary theorists; these difficulties will be referred to later in connection with Milton Friedman's restatement of the quantity theory.

The fourth development stemming from Keynes' theory of the demand for money has been the disaggregation of assets other than money and the elaboration of liquidity preference theory into a general theory of the relative prices of (rates of return on) assets of different types. The chief contributions in the direct line of Keynes' own

question would have the same alternative of investing its idle cash at interest, and react the same way. Turvey also argues [121, pp. 28-30] that an increase in the level of a unit's transactions will raise transactions demand only in a probability sense, since there may be an offsetting change in the timing-structures of the unit's payments and receipts.

thought, by Joan Robinson [98] and Richard Kahn [63], are primarily concerned with reasserting Keynes' view that the long-term rate of interest is determined by expectations about the future long-term rate, against Hicks' dismissal of it as a bootstrap theory and his attempt to explain the long-term rate as an average of expected short-term rates [60, pp. 163-64]. Robinson and Kahn both employ a division of assets into cash, bills, bonds, and equities, and a classification of asset-holders into contrasting types according to whether their asset preferences are dominated by capital-uncertainty or income-uncertainty; but Robinson is concerned to set the argument against the background of a growing economy, while Kahn concentrates on a rather subtle analysis of the interaction of the precautionary and speculative motives.

In contrast, U.S. contributions have been prompted by concern with the problems posed for monetary, fiscal, and debt-management policy by the wartime legacy of a large public debt of short average maturity; two early articles influential in subsequent thinking were those of Roland McKean [80] and Richard Musgrave [87]. The common feature of subsequent work is the treatment of assets as possessing varying degrees of liquidity, and the application of general equilibrium theory to the determination of their relative prices (yields), which are treated as the outcome of the interaction of asset preferences and the relative quantities of the different assets available. This approach (which is also central in the analysis of Robinson and Kahn just mentioned) is exemplified in W. L. Smith's study of debt management for the Joint Economic Committee [110] and Ralph Turvey's book on interest rates and asset prices [121]. The latter is notable for its explicit general equilibrium approach and its careful attention to the requirements of consistent aggregation. The formulation of monetary theory as part of a more general theory of asset holding has been carried farthest by the group working at Yale University under the inspiration of James Tobin; their "portfolio-balance" approach has been strongly influenced by Harry Markowitz's work on rational investor behavior (notably [77a]). Unfortunately little of this group's work is yet available in print (see, however, Tobin [113] [115] [116]).

The formulation of the general-equilibrium approach to the theory of asset prices and yields in the literature just described has some implicit biases which are apt to mislead the unwary, especially in its application to the analysis of the term structure of interest rates.¹⁰ In the

¹⁰ This phrase has reference to the pattern of rates on loans of successively longer maturity; statistically it is represented by the "yield curve," which charts the yields on government debts against their maturities. In the English literature the problem appears as that of the relation between the long and the short rate of interest (the bill rate and

first place, there is a tendency to follow too closely Hicks' original sketch of the approach [59] in identifying the typical asset-holder with a bank, borrowing for a shorter term than it lends and therefore preferring the shorter-term assets. In the second place, emphasis on the slippery and ill-defined quality of liquidity as the characteristic differentiating alternative assets tends to divert attention from the linkage of asset markets by speculation, and so to exaggerate the sensitivity of the interest-rate pattern to changes in the relative quantities of assets.¹¹ In this connection it is appropriate to refer briefly¹² to some recent work on the term structure of interest rates by John Culbertson [29] and Joseph Conard [24, Part III], which on its empirical side contributes to filling the gap noted by Villard [123, pp. 336-37] between the theory and the historical facts of interest-rate behavior. Both authors arrive at essentially the same major result, that short and long rates tend to move together in a rational way, though Culbertson regards his analysis as contradicting the classical "expectations" theory whereas Conard regards his as confirming a modified version of it. The explanation of this difference is that Culbertson identifies accepted theory with the incorrect Hicks-Lutz formulation of it, according to which the investor is depicted as choosing between holding a bond to maturity and investing in successive short-term loans over the same period, whereas Conard identifies it with the correct formulation, in which the investor compares the expected yields (including interest and changes in capital value) of alternative assets over the period for which he expects or is obliged to remain invested. A more recent study by David Meiselman [81] advances both the theory and explanation of the rate structure (and incidentally refutes one of Culbertson's main arguments against the expectations theory) by interpreting the yield curve as expressing expected future short-term rates and explaining changes in it as the market's reaction to errors of expectation.

B. *Restatement of the Quantity Theory*

While Keynes' formulation of the theory of demand for money has been evolving in the directions just described, a fundamentally very similar formulation has been developed by a group of scholars asso-

the bond rate), a reflection of the institutional fact that the British government obtains its short-term financing predominantly by three-months bills of exchange, and has a substantial volume of perpetual debt ("consols") outstanding.

¹¹ The sensitivity of the rate pattern to changes in the relative quantities of short-term and long-term debt is the crucial empirical issue in some recent controversies about monetary policy, especially the "bills only" policy.

¹² Shackle's survey of interest theory [105], to which the reader has been referred in the introduction, unfortunately makes very little reference to rate-structure theory, presumably because it has not been discussed recently in English journals. The interested reader is referred to Conard's useful book [24].

ciated with the University of Chicago, inspired by Milton Friedman and claiming allegiance to the quantity theory as handed down in the oral tradition of that institution. The most complete statement of this group's basic theory—which tends usually to be mentioned only briefly in the course of presenting the results of empirical research—is contained in the condensed and rather cryptic restatement of the quantity theory by Friedman that introduces four of their empirical studies [41], a restatement that takes the reader at a hard pace from the fundamental theory to the simplifications required for its empirical application. The central points in the restatement are that the quantity theory is a theory of the demand for money, not of output, money income, or prices; and that money is an asset or capital good, so that the demand for it is a problem in capital theory. In formulating the demand for money as a form of capital, however, Friedman differs from the Keynesian theorists in starting from the fundamentals of capital theory. He begins with the broad concept of wealth as comprising all sources of income, including human beings, and relates the demand for money to total wealth and the expected future streams of money income obtainable by holding wealth in alternative forms. Then, by a series of mathematical simplifications, approximations of nonobservable variables (of which the most important is the representation of the influence of human wealth by the ratio of nonhuman to human wealth), simplifying economic assumptions, and rearrangements of variables, he arrives at a demand function for money which depends on the price level, bond and equity yields, the rate of change of the price level, income, the ratio of nonhuman to human wealth, and a taste variable; finally, he makes neat use of the homogeneity assumption to show that the demand for real balances depends only on real variables and that it can be reformulated as a velocity function depending on the same variables.

In its final form, Friedman's demand function for money is hard to distinguish from a modern Keynesian formulation, especially in view of his remark that the nonhuman to human wealth ratio "is closely allied to what is usually defined as the ratio of wealth to income" [41, p. 8]. The apparent similarity is misleading, however, because what comes out as income originally entered as wealth, i.e. capitalized income, the process of capitalizing it being absorbed by Friedman's simplifications into the yield and wealth-ratio arguments of the function; and, as Friedman indicated by various remarks and has since demonstrated by the application of his permanent income concept to the explanation of the behavior of velocity [38], the "income" relevant to this equation is not income as measured in the national accounts but income conceived of as the net return on a stock of wealth, or wealth

measured by the income it yields. The use of "income" to represent what is really a wealth variable has incidentally contributed to some minor confusions of stock and flow concepts in the writings of Chicago monetary theorists, especially in the alternative formulation of the theory of demand for money as an application of demand theory developed by Richard Selden [104], where money rather than its services is described as the good demanded, the elasticity relating changes in the stock of money demanded to changes in the flow of income is described as an income-elasticity, and money is classed on the basis of the empirical magnitude of this elasticity as a luxury good.

Friedman's application to monetary theory of the basic principle of capital theory—that income is the yield on capital, and capital the present value of income—is probably the most important development in monetary theory since Keynes' *General Theory*. Its theoretical significance lies in the conceptual integration of wealth and income as influences on behavior: Keynes ignored almost completely the influence of wealth, as was legitimate in short-period analysis; and while subsequent writers in the Keynesian tradition have reintroduced wealth they have generally followed the Cambridge practice of restricting wealth to nonhuman property, a practice which encourages uncritical treatment of wealth and income as entirely independent influences on behavior. In consequence, as mentioned earlier, much of the recent monetary literature contains formulations of the demand for money relating it to income, wealth, and the rate of interest, variables which are in fact interdependent and the use of which in this way involves inelegant redundancy and promotes errors in both theoretical reasoning and empirical applications.

The most important implication of Friedman's analysis, however, concerns not the formulation of monetary theory but the nature of the concept of "income" relevant to monetary analysis, which, as explained above, should correspond to the notion of expected yield on wealth rather than the conventions of national income accounting. This concept Friedman has elaborated under the name of "permanent income," and employed in his theory of the consumption function [35] and subsequent empirical work on the demand for money [38]. The statistical application of it has involved estimating expected income from past income, which means that empirically the theory is very similar to theories employing lagged income as a determinant of behavior.¹³ This similarity exemplifies a serious problem in the empirical application and testing of economic theories—the theoretical

¹³ These brief remarks do justice neither to Friedman nor to other consumption theorists, a number of whom have been working towards similar theories (see Johnson [61]).

interpretation of empirical results—which is especially acute in the interpretation of empirical findings on the demand for money because of the interrelationship of income, wealth, and interest.

C. The Distinguishing Characteristics of Money

While the treatment of money as an asset distinguished from other assets by its superior liquidity is common ground among contemporary theorists, the transition from the conception of money as a medium of exchange to money as a store of value has raised new problems for debate among monetary theorists. These problems result from recognition of the substitutability between money (conventionally defined as medium of exchange) and the wide range of alternative financial assets provided by government debt and the obligations of financial institutions, and between money and the access to credit provided by an elaborate credit system, in a financially advanced economy. They concern the related empirical questions of the definition of an appropriate monetary magnitude, and the specification of the variables on which the demand for the selected magnitude depends, questions that pose little difficulty when money is defined as the medium of exchange and its velocity is assumed to be determined by institutional factors. These questions lead into the fundamental question of the importance of the quantity of money in monetary theory and monetary policy, since unless the demand for money—defined to correspond to some quantity the central bank can influence—can be shown to be a stable function of a few key variables, the quantity of money must be a subordinate and not a strategic element in both the explanation and the control of economic activity. Argument and opinion about these issues have frequently been clouded by confusion between constant velocity and a stable velocity function, and between elasticity and instability of the function. In discussing them, it is convenient to describe first the main schools of thought on these issues,¹⁴ and then the empirical research bearing on them.

At the cost of some arbitrary oversimplification, one can distinguish broadly four main schools of thought. At one extreme are those who continue to find the distinguishing characteristic of money in its function as medium of exchange, and define it as currency plus demand deposits adjusted [73]. Next to them are the Chicago quantity theorists, who define the function of money more broadly as a temporary abode of purchasing power,¹⁵ and in their empirical work define money

¹⁴ To keep the bibliography within reasonable bounds, the references below are confined as far as possible to authors who have supported their theories with empirical research, or to recent writings.

¹⁵ The phrase is Milton Friedman's.

as currency plus total commercial bank deposits adjusted, largely to obtain a consistent long statistical series [104] [38]. Both schools believe that there is a stable demand for money (velocity function), though they define money differently. A third school, at the opposite extreme, consists of those, usually specially interested in monetary policy rather than theory as such, who carry recognition of the similarity between money and other realizable assets or means of financing purchases to the point of rejecting money in favor of some much broader concept, measurable or unmeasurable. A measurable concept is exemplified by the long-established Federal Reserve Board theory that what matters is the total amount of credit outstanding, the quantity of money exercising an influence only because bank credit is a component of total credit (see for example [57, pp. 261-63 and 272-76]). An unmeasurable concept is exemplified by the Radcliffe Committee's concept of the liquidity of the economy [127, Ch. 6], the theory of which was left unexplained in its Report but has since been expounded by Richard Sayers [101]; according to this more extreme theory velocity is a meaningless number, the economy being able to economize on money by substituting credit for it without limit [127, p. 133]. This school, in both its variants, does not so much advance a theory as assert a position that implies a highly elastic, complex, or unstable velocity function. The serious controversy of recent years has been aroused by a fourth school, in between those already mentioned, which has been concerned with the implications for velocity of the presence of a substantial volume of liquid assets closely substitutable for money. In the early years after the war, this school was mainly concerned with the influence of short-term public debt; since the mid-'fifties, the centre of attention has shifted to the liabilities of nonbank financial intermediaries.

✓ The leading figures in this last development are J. G. Gurley and E. S. Shaw, who in a series of contributions [50] [51] [53] culminating in a major theoretical work [52] have developed an analysis of the role of finance and particularly of nonbank financial intermediaries in economic development which has important implications for monetary theory. Gurley and Shaw start from the fact that real economic development is accompanied by a process of financial development in which primary securities (those issued to finance expenditure) become differentiated and there emerge financial intermediaries—of which commercial banks are only one variety—whose function is to enable asset holders to hold primary securities indirectly in the more attractive forms of liabilities issued by the intermediaries. Contrary to the main stream of both classical and Keynesian monetary theory, which treats the financial structure as of secondary importance and relates

the demand for money to the long-term rate of interest or to the rate of return on real capital, Gurley and Shaw maintain that monetary theory must take account of these details of financial organization and development, since they affect the demand for money. In particular, they argue that because nonbank financial intermediaries generally offer liabilities which are closer substitutes for money than for primary securities, and hold small reserves of money themselves, their growth tends to reduce the demand for money. One implication of this analysis, which comes out more strongly in their remarks on monetary policy than in their theory,¹⁶ but to which they do not in fact commit themselves, is that the "quantity of money" relevant for monetary theory and policy should include the liabilities of nonbank financial intermediaries.

Gurley and Shaw's work has provoked a number of critical journal articles, but those most specifically concerned with their theoretical analysis of the influence of nonbank intermediaries on the demand for money (by Culbertson [27] and Aschheim [3]) misunderstand both Gurley and Shaw's argument and the theory of credit creation.¹⁷ The important question Gurley and Shaw raise is the empirical one of whether explanation of the demand for money requires introduction of the amounts of or yields on nonbank intermediary liabilities. This requires an elaborate statistical analysis of the demand for money and other assets which they have not yet produced. In [53] they show only that the facts of financial development in the United States can be rationalized by their theory; and Gurley's independent demonstration [49] that interest rates in the postwar period can be explained on the assumption that an increase in liquid assets reduces the demand for money by half as much—that is, that a correspondingly weighted sum of money and liquid assets can be used to represent the "quantity of money" in applying monetary theory—does not prove that money alone would do less well; indeed Gurley explains in an Appendix why money alone could have been used. The results of recent empirical research on the demand for money and velocity by other economists described

¹⁶ Gurley and Shaw believe that present methods of credit control discriminate against banks in their competition with nonbank intermediaries, weakening the effectiveness of monetary policy over the long run, and unlike most of their critics are prepared to contemplate extension of the central bank's regulatory powers.

¹⁷ Patinkin's review [91] of the book translates Gurley and Shaw's argument into his own language and interprets the effect of financial intermediation as an increase in the liquidity of bonds which decreases the demand for money and increases its interest-elasticity. Alvin Marty's review [78] makes the interesting theoretical point that the introduction of a substitute does not necessarily increase the elasticity of demand. Neither reviewer notices that Gurley and Shaw infer increased elasticity only in the special case of an unfunding of government debt, and present a satisfactory reason for it [52, pp. 162-66].

below tend to contradict Gurley and Shaw's contention, since the writers concerned find it possible to explain the demand for money without reference to the variety of alternative assets and do not discover the downward trend in demand for money implied by Gurley and Shaw's thesis. This is, however, only an indirect test; and the empirical research in question is itself controversial.

D. *Empirical Research on the Demand for Money*

Prior to the *General Theory*, empirical research on velocity was primarily concerned with the measurement of the institutional determinants of transactions velocity; since then, attention has shifted to econometric explanation of income velocity and its alternative formulation, the demand for money,¹⁸ one of the prime objects being to determine the existence or otherwise of the Keynesian liquidity trap. An influential early contribution by James Tobin [114] followed Keynes' theory in estimating idle balances by subtracting from total deposits an estimate of active balances derived from the maximum recorded velocity of circulation, and found a rough hyperbolic relationship between idle balances and interest rates, implying a liquidity trap. This relationship broke down for the postwar years, one reason being its failure to include the influence of total wealth; and subsequent researchers have generally preferred to avoid its assumption of a separable and proportional transactions demand in favor of analyzing the total demand for money. Tobin's method has, however, been employed in a more sophisticated form in a recent major study by Martin Bronfenbrenner and Thomas Mayer [13], which relates the demand for idle money (total money being defined as currency plus demand deposits adjusted) to the short-term interest rate, wealth, and idle balances of the previous year. They find that the last two variables explain most of the fluctuations in idle balances, and that the demand for idle balances is interest-inelastic with no tendency for the elasticity to increase as the rate falls. They interpret this last result as evidence against the liquidity trap; the validity of this inference depends on whether the liquidity trap is identified with infinite elasticity at some positive interest rate or an unlimited increase in the quantity of money demanded as the interest rate falls.

Estimates of the total demand function for money, besides avoiding arbitrary assumptions about transactions velocity, are easier to relate to income velocity than estimates of the Tobin type, since they usually

¹⁸ For discussion of the earlier literature, see Villard [123] and Selden [104]; a useful survey of the econometric studies preceding their own work is given by Bronfenbrenner and Mayer [13]. The more traditional type of research on transactions velocity has been continued by a number of contemporary economists, notably George Garvey [46].

use income as one of the explanatory variables.¹⁹ Among a number of such estimates the two most important, in terms of length of period covered, simplicity of the demand function fitted, and intrinsic theoretical interest, are those by Henry Latané [73] and Milton Friedman [38]. Latané, adopting what he called a pragmatic approach to the constant-velocity and Keynesian formulations of demand for money, found that a simple linear relationship between the ratio of money (currency plus demand deposits) to income and the reciprocal of high-grade long-term interest rates fitted the historical data closely. Friedman's contribution builds on Selden's earlier finding [104] that the secular decline in velocity could be explained by the hypothesis that the demand for money (currency plus total commercial bank deposits) increases more rapidly than income (money is a "luxury good"), a finding apparently inconsistent with the fact that income and velocity vary together over the cycle. Friedman resolves the paradox by hypothesizing that the demand for real balances is an elastic function of permanent income, and showing that the apparent inconsistency of the cyclical behavior of velocity with this hypothesis disappears when the expected income and expected prices indicated by the theory are used instead of their observed counterparts; moreover, since this empirical analysis explains velocity without introducing interest rates into the demand function for money, it seems to dispose of the liquidity trap.

These two empirical demand functions for money apparently conflict, in that Latané's depends on both income (with a unitary income elasticity) and the long-term interest rate, whereas Friedman's depends only on income, with an income-elasticity substantially above unity. But there is no necessary conflict, since Friedman's definition of money includes time deposits, and may therefore absorb most of the substitution between demand deposits and currency and interest-bearing assets induced by interest-rate changes. The real issue is which definition of money gives the better empirical results. Latané has since shown [74] that his formulation fits the subsequent data well. He explains the difference between the income-elasticities of the two functions by the facts that over the period covered by Friedman's calculations time deposits (whose inclusion he questions on theoretical grounds) grew more rapidly than demand deposits, and the long-term interest rate declined from 6.4 to 2.9 per cent. (Latané also adduces evidence for the existence of a liquidity trap, though he prefers to explain it by the cost of bond transactions rather than by Keynes' speculative motive.) Friedman's demand function, by contrast, does not fit the subsequent data, since the secular decline in velocity has reversed

¹⁹ An interesting exception is Harold Lydall's derivation of the demand for money from the hypothesis of a constant ratio of liquidity to wealth [77].

itself (Latané's analysis would attribute this to the subsequent upward movement of interest rates). Friedman has since been experimenting with an extended permanent income hypothesis that allows for changes in the confidence with which expectations are held [37]. Latané's demand function, incidentally, can be used to illustrate the difficulty of interpretation mentioned earlier: if wealth is assumed to be measured by income capitalized at the long-term interest rate, the quantity of money demanded in Latané's function can be expressed alternatively as a function of interest and wealth or of wealth and income,²⁰ thus being consistent with a variety of theoretical formulations.

The empirical studies of demand for money just discussed have a bearing on the fundamental issue, the subject of continued controversy in the history of monetary theory: whether monetary theory is more usefully formulated in terms of the demand for and supply of money or of the influence of money on expenditure and income—the equation-of-exchange approach or the income-expenditure approach. This issue, which Keynes' promulgation of the propensity to consume as a behavior relationship more stable than the discredited velocity of circulation seemed to have settled finally in favor of the income-expenditure approach, has become less settled with the postwar failure of the simple consumption function and the increasing complexity of Keynesian models on the one hand, and the increasing sophistication of modern adherents of the velocity approach on the other.

The counterattack on Keynesian income theory first launched by Friedman [36] [41] has been carried further in an article by Friedman and Gary Becker [43], which argues that the proper test of Keynesian theory is not the stability of the consumption function but its ability to predict consumption from investment, and produces some evidence that the investment multiplier is a poorer predictor of consumption than is the trend of consumption. In reply, Lawrence Klein [67] and John Johnston [62] have argued that a proper test should be concerned with the sophisticated and not the naive version of a theory, and should test the predictive power of the complete model and not just one part of it. This preliminary skirmish probably indicates the main lines of the battle that is likely to follow publication of a major study by Friedman and David Meiselman [44], which shows by exhaustive statistical tests on U.S. data since 1897, that except for

²⁰ In [74] Latané uses a linear relationship between income velocity and the rate of interest, $V = .77r + .38$, where $V = M/Y$, the quantity of money divided by income. This yields the demand function for money, $M = Y/ (.77r + .38)$. Using the definition $W = Y/r$, this can be written equivalently as

$$M = \frac{W}{.77 + .38/r} \quad \text{or} \quad M = \frac{W}{.77 + .38W/Y}$$

the 1930's, the quantity of money has been a better predictor of consumption than has autonomous spending.

These results pose an important theoretical problem, since they imply that a change in the quantity of money that has no wealth-effect nevertheless will have an effect on consumption even though it has no effect on interest rates. The difficulty of understanding how this can be prompted the dissatisfaction of Keynes, Wicksell, and other income-expenditure theorists with the quantity theory, and provides the hard core of contemporary resistance to it. Friedman and Meiselman's explanation of their results may therefore initiate a new and possibly fruitful debate on how money influences activity.

III. *The Supply of Money, Monetary Control, and Monetary Dynamics*

A. *The Supply of Money*

The theory of money supply is virtually a newly-discovered area of monetary research. The general practice in monetary theory has been to treat the quantity of money as determined directly by the monetary authority, without reference to the links intervening between reserves provided by the central bank on the one hand, and the total of currency and bank deposits on the other. This treatment has rested on a mechanical analysis of the determination of money supply, very similar to the outmoded treatment of velocity, in which the money supply is related to the reserve base by a multiplier determined by the reserve ratio observed by the banking system, and the ratio between currency and deposits held by the public. In conformity with developments on the side of demand, the trend of recent research on money supply has been towards treating these ratios as behavior relationships reflecting asset choices rather than as exogenous variables, and elaborating the analysis to include the part played by other financial intermediaries than commercial banks, in the process evolving a less mechanical theory of central bank control. In part, recent developments in this area reflect a more general tendency to formulate the dynamics of monetary change in terms of the adjustment of actual to desired stocks rather than in terms of changes in flows.

Though Keynes followed convention in treating the quantity of money as a direct policy variable, other monetary theorists (an early example is Kragh [70]) applied the notion of liquidity preference to the reserve behavior of banks, and the same idea has been incorporated in various Keynesian models (not always consistently) by making the money supply vary with the rate of interest. Theorists concerned with the money supply have, however, tended until recently to stick to the mechanical "money multiplier" approach, extending it

to allow for the different reserve requirements against time and demand deposits and the demand for money by financial intermediaries; and empirical research has followed the same line, partitioning changes in the quantity of money among changes in the currency-deposit and reserve-deposit ratios and the reserve base, and changes in the reserve base among changes in reserve bank liabilities and assets. These techniques can be extremely fruitful—notable examples are Donald Shelby's investigation of the monetary implications of the growth of financial intermediaries [107], and Brunner's empirical study of U.S. monetary policy in the middle 1930's [15]—but asset ratios are a crude technique for representing behavior relationships.

Philip Cagan's study of the demand for currency relative to the total money supply [19] has broken new ground in attempting an economic explanation of the ratio of currency to currency plus total deposits. Cagan examines a number of possible determining factors, and finds that expected real income per capita explains most of the decline in the ratio from 1875 to 1919, while changes in the net cost of holding currency instead of deposits explain most of the variation in the ratio from 1919 to 1955, though the rate of personal income tax (taken to represent the possible gain from tax evasion permitted by using currency for transactions) is required to explain the rise in the currency ratio in the Second World War.

Other researchers have concerned themselves with the response of the banking system to changes in reserves, though so far the published results have been theoretical rather than empirical. Recent work on this problem has departed from the "money-multiplier" approach in three respects: first, in basing the analysis on the behavior of the individual bank instead of the banking system; second, in applying economic theory to the explanation of the level of reserves desired by the bank and relating its behavior in expanding or contracting its assets to the difference between its actual and its desired reserves; and third, in treating the loss of reserves consequent on expansion as a stochastic process. These innovations are exemplified in two recent articles, both intended as a basis for empirical research: Brunner's schema for the supply theory of money [16], the central feature of which is a relationship between a bank's surplus reserves and its desired rate of change in its asset portfolio, formulated in terms of a "loss coefficient" measuring the (probable) loss of surplus reserves per dollar of asset expansion; and Daniel Orr and W. J. Mellon's analysis of bank credit expansion [89], which applies inventory theory to the bank's holding of reserves against cash losses (which are assumed to be random and normally distributed). Orr and Mellon show, in contrast to the results of money-multiplier analysis, that the marginal expansion ratio will be lower than the average for a monopoly bank,

and lower for a banking system than for a monopoly bank; and that for a banking system the marginal expansion ratio depends on the distribution of the additional reserves among banks.

B. *Monetary Control: A Theoretical Issue*

The research just mentioned is concerned with introducing into the theory of money supply recognition of the fact that commercial banks are profit-maximizing institutions with economic behavior patterns on which the central bank must operate to control the money supply. The fact that monetary control operates in this way is the source of one group of issues in recent discussions of monetary policy, to be described in the next section; it also poses the interesting theoretical question of what powers the central bank needs to control the price level. This question has been raised and discussed by Gurley and Shaw [52, Ch. 6], who conclude their book by contrasting monetary control in a private commercial banking system with their standard case, in which the government determines the nominal quantity of money and the deposit rate on it. Unfortunately their argument is nonrigorous and inconsistent: having shown [52, pp. 261-62] that control of the nominal quantity of bank reserves and the rate of interest paid on these reserves is sufficient for control of the price level (though they argue that this control is weaker than in their standard case because bank liquidity preferences or deposit rates may change independently of central bank action), they conclude their discussion of the technical apparatus of monetary control with the statement that "of three indirect techniques—fixing nominal reserves, setting the reserve-balance rate, and setting members' own deposit rate—the Central Bank can get along with any two in regulating all nominal variables in the economic system" [52, pp. 274-75].²¹ Patinkin [91, pp. 112-16] has shown that this statement is incorrect, and that the central bank needs to control nominal reserves and one of the interest rates.²²

C. *Monetary Dynamics*

As mentioned above, one of the recent innovations in the theory of money supply is the analysis of bank response to changes in reserves in terms of the adjustment of actual to desired reserves. This way of stating the problem reflects a more general tendency toward

²¹ Gurley and Shaw also state as a prerequisite of monetary control that the authorities take steps to ensure the moneyness of bank deposits; the necessity for this is debatable.

²² Patinkin goes on to argue that price-level determinacy requires fixity of one nominal quantity and one yield, and would be secured by fixity of the nominal quantity of (non-interest-bearing) outside money; and that therefore Gurley and Shaw should have considered the means by which the central bank changes the price level, instead of the powers required to determine it. This argument raises the question discussed earlier, of the usefulness of founding monetary theory on the real-balance effect.

the formulation of monetary dynamics in terms of adjustment of actual to desired stocks, associated in turn with the formulation of monetary theory in terms of asset choices as described in the previous section. This tendency has developed somewhat apart from, and has been concerned with more fundamental issues than, the controversy over the interrelated issues of stock versus flow analysis and liquidity-preference versus loanable-funds theories that has broken out anew since the war. Much of the relevant literature on the latter subject has been surveyed by Shackle [105]; unfortunately, Shackle's discussion of the issues is vitiated by the erroneous belief that the presence of both a stock of old securities and a flow of new securities implies a conflict of forces—stock demand and supply, and flow demand and supply—operating on the interest rate, and that this conflict poses a dilemma for monetary theory that can only be resolved by the postulation of two rates of interest. It is therefore necessary to describe the controversy briefly, before turning to the more important development in monetary dynamics.

Modern controversy over liquidity-preference versus loanable-funds theories starts from Hicks' demonstration of the formal equivalence of the two [60, pp. 160-62]; Hicks used the fact that Walras' Law permits the elimination of one of the equations in a general equilibrium system to argue that one can omit either the excess-demand-for-money equation, leaving a loanable-funds theory of interest, or the excess-demand-for-securities equation, leaving a liquidity-preference theory of interest. The omitted equations are flow equations; William Fellner and Harold Somers [33] subsequently showed that they could be identified with the desired change in the stock of money or securities over the market period, so that flow analysis and stock analysis of monetary equilibrium were equivalent. Fellner and Somers also argued in favor of the loanable-funds theory and against the liquidity-preference theory that, as the rate of interest is the price of securities, it is more sensible to regard it as determined by the demand for and supply of securities than by the demand for and supply of money. This led to a controversy with L. R. Klein [68], who objected to Fellner and Somers' assumption that the period of analysis starts with equilibrium between actual and desired stocks as begging the question of stock versus flow theory, and declared that the real difference between the liquidity-preference and loanable-funds theories was a dynamic one, liquidity-preference theory maintaining that the rate of interest would change in response to an excess demand for or supply of money, not an excess supply of or demand for securities [68, pp. 236-41].²³

²³ An excess demand for money does not necessarily imply an excess supply of securities, since it may be accompanied by an excess supply of goods.

In commenting on the controversy, Brunner [68, pp. 247-51] pointed out that Fellner and Somers' analysis, while correct, evaded the real issue that Klein was raising—that there is a difference between the dynamic adjustment processes of markets in which the object of demand is primarily a stock to be held, and of those in which the object of demand is primarily a flow to be consumed; but he sided with Fellner and Somers against Klein on the dynamic determinants of interest-rate changes. Earlier, Lerner had produced a much-quoted but untraceable objection to Hicks' original argument: that if the excess demand equation for some commodity (Lerner chose peanuts) is eliminated by Walras' Law, the resulting system includes both a loanable-funds and a money equation, one of which must be used to determine the price of the excluded commodity.

Subsequent contributors to the debate can be classed as those who maintain the identity of the two theories, and those who maintain that the liquidity-preference theory is different from (and superior to) the loanable-funds theory. To clarify the issues, it is convenient to discuss these groups in order. Among the former group, S. C. Tsiang [119], W. L. Smith [111], and Don Patinkin [92] deserve mention—Smith for his compact exposition and explicit recognition of the difference between stock and flow theories of behavior.

Tsiang objects to the Hicks-Fellner and Somers use of Walras' Law to establish the equivalence of the two theories on the Lerner grounds that this law only permits the elimination of one of the general equilibrium equations, and maintains that to establish the equivalence it is necessary to show that the individual can only demand or supply securities by supplying or demanding money. He also objects that the flow demand and supply of money in the Fellner-Somers analysis bears no relation to the stock demand and supply of Keynesian theory. To get around these difficulties (which, as Patinkin [92] shows, are of Tsiang's own creating) Tsiang chooses a period so short that the economic unit cannot plan on using its proceeds from planned sales of commodities to finance planned purchases of them; by this arbitrary device the flow and stock demands for money are equated and the only choice left to the unit is between holding cash (as an idle balance or for spending) and holding securities, so that identity of the two theories (in Tsiang's sense) necessarily follows.

Patinkin's article is an elegant restatement of the Hicksian position. Patinkin argues that the Lerner objection merely means that it is wrong to classify interest theories by the equation omitted, and that the two theories are simply alternative formulations of one general equilibrium theory of interest. He disposes of Tsiang's objection to the Fellner-Somers analysis by showing that the excess flow-demand for money is identical with the excess stock-demand for money for the

period (Patinkin slips in not making explicit that to translate a desired change in a stock over a period into a flow during the period it is necessary to divide the change by the length of the period). Finally, he disposes of Klein's statement of the difference between the two theories by showing that this difference refers to the dynamic behavior of the same market—the securities market—so that the choice of which market to eliminate is not relevant.

Patinkin goes on to argue, with the help of the apparatus of dynamic theory developed in his book, that the Klein hypothesis concerning the dynamics of the interest rate is inherently implausible, since it implies that the interest rate will fall (rise) in the face of excess supply (demand) in the securities market. This argument, appealing as it is, is restricted by its dependence on Patinkin's dynamic apparatus, which permits simultaneous disequilibrium in all markets and relates the direction of movement of individual prices to the excess demand or supply in the corresponding markets. It can be objected both that there is no reason why the movement of price in a market should be dominated by the excess demand or supply in that market (Brunner's argument against Klein recognized this point [68, p. 251]) and that a dynamic analysis of price movements in one market requires specification of how disequilibria in the remaining markets are resolved.²⁴ Further, in setting up a dynamic analysis—particularly a period analysis—explicitly allowing for the (temporary) resolution of disequilibrium, it is possible and sometimes convenient to define the relationships in such a way that Walras' Law does not hold. This is the procedure that has been adopted (implicitly or explicitly) by recent defenders of the liquidity-preference theory: Joan Robinson's exposition of it [98] employs a period analysis in which retailers confronted with unintended increases in inventories finance themselves by releasing cash or securities, and Hugh Rose's dynamic version of Keynes' theory [100] (which behaves according to Klein's hypothesis) uses the same model with inventories being financed by security issues. In both cases the demand and supply of goods are equated *ex post* by the accommodating behavior of retailers, but this behavior is not included in the *ex ante* description of disturbances to equilibrium. F. H. Hahn's reformulation of the liquidity-preference theory as a theory of the ratios in which cash and securities are held [55] employs a similar but more subtle device—a distinction between the investment-planning period, and a shorter "investment-financing" period during which the loanable-funds but

²⁴ Patinkin recognized these difficulties in the discussion of dynamic stability in his book [93, pp. 157-58], and admitted that they made stability a matter of assumption rather than of proof; but he overlooked them in applying his dynamic apparatus to the liquidity-preference loanable-funds controversy.

not the liquidity-preference theory applies—to reconcile the two theories dynamically.

Elegant as it is, Patinkin's analysis is confined to the determination of equilibrium in a single period, and ignores the effects of the changes in stocks determined in that period on the equilibrium determined in the next period. Other participants in the controversy have followed him (or rather Keynes) in abstracting from the process of accumulation of real and financial wealth. The discussion has therefore stopped short of the issue raised by Klein, and elaborated on by Brunner, of the dynamics of price in a market characterized by a large stock and small demand-and-supply flows per period. Brunner [68, pp. 247-49] sketched a theory of such a market; in this theory price is determined at every moment by the demand for the existing stock, but at this price there may be a net flow demand or supply which gradually changes the existing stock and therefore the price; and full equilibrium requires a price which both equates the stock demand and supply and induces a zero net flow.²⁵ A very similar theory has since been elaborated by Robert Clower [22], who uses it to argue that productivity and thrift have only an indirect effect on interest (through the net flow of new securities) unless they affect the stock demand for securities directly by changing expectations. Clower and D. W. Bushaw [23] have produced a general theory of price for an economy that includes commodities appearing only as stocks, commodities appearing only as flows, and commodities appearing as both stocks and flows; in this theory the equilibrium price in the market for a stock-flow commodity must equate both the desired and actual stock and the flow demand and supply, and in the dynamic analysis the rate of change of price depends on both the excess-stock and excess-flow demands.²⁶

Neither the Brunner-Clower nor the Clower-Bushaw theory really solves the stock-flow problem: the former subordinates the flow analysis entirely to the stock, the latter simply adds stock and flow analyses together. The defect common to both is the absence of a connection between the price at which a stock will be held and the current rate

²⁵ In describing a mathematical model of this theory, Brunner admits two possible situations of partial equilibrium—stock equilibrium and flow disequilibrium and the converse—but nevertheless asserts that the stock relation determines momentary price in both. This inconsistency, which was presumably prompted by his intention to contrast the adjustment processes of markets dominated respectively by stocks and flows, is the source of the dilemma Shackle finds between stock and flow equilibrium as the determinant of price [105, p. 222].

²⁶ Cliff Lloyd [75] has argued that the presence of two equilibrium equations for a stock-flow commodity may invalidate the Hicksian proof of the equivalence of the loanable-funds and liquidity-preference theories. It may be noted that the Clower-Bushaw theory provides a formal solution to the apparent dilemma created by Brunner's alternative partial equilibria.

of change of the stock held, and correspondingly between the price at which a stock will be supplied and the current rate of change of the stock supplied; such connections would yield a simultaneous equilibrium of stock and flow evolving towards full stock equilibrium (zero net flow).²⁷ The addition of such connections would require treating savings and investment as processes of adding to stock, rather than as flows as they have customarily been treated in the post-Keynesian literature.²⁸

This is the approach to monetary dynamics that has been emerging in the past few years, from both "Keynesian" and "quantity" theorists, as an outgrowth of the formulation of monetary theory as part of a general theory of asset holding. The essence of the new approach, elements of which are to be found in recent works of such diverse writers as Cagan [20], Tobin [116], Friedman [40, pp. 461-63] and Brunner [18], is to view a monetary disturbance as altering the terms on which assets will be held (by altering either preferences among assets or the relative quantities of them available), and so inducing behavior designed to adjust the available stocks of assets to the changed amounts desired.²⁹ The new approach has been aptly summarized, from the point of view of monetary policy, by Brunner [18, p. 612]:

Variations in policy variables induce a reallocation of assets (or liabilities) in the balance sheets of economic units which spills over to current output and thus affect the price level. Injections of base-money (or "high-powered" money) modify the composition of financial assets and total wealth available to banks and other economic units. Absorption of the new base money requires suitable alterations in asset yields or asset prices. The banks and the public are thus induced to reshuffle their balance sheets to adjust desired and actual balance-sheet position.

The interaction between banks and public, which forms the essential core of money-supply theory, generates the peculiar leverage or multiplier effect of injections of base money on bank assets and deposits and, correspondingly, on specific asset and liability items of the public's balance sheet. The readjustment process induces a change in the relative yield (or price) structure of assets crucial for the transmission of mone-

²⁷ In one passage [105, p. 223] Shackle outlines a solution to his dilemma along these lines, but does not pursue it further. The Brunner-Clover theory can (with some difficulty) be interpreted as a special case of the general theory, one in which the price at which a stock is held is independent of the current rate of change in the stock.

²⁸ This observation refers to the literature on the Keynesian general equilibrium system, and not to the specialist work on consumption and investment, where the treatment of saving and investment as processes of adding to stock has become well established since the war.

²⁹ While this approach can be described as new in relation to the time-period included in this survey, it can from another point of view be regarded as a development of certain strands in Keynes' thought [65, Vol. I, pp. 200-09] [66, Ch. 11].

tary policy-action to the rate of economic activity. The relative price of base money and its close substitutes falls, and the relative price of other assets rises.

The stock of real capital dominates these other assets. The increase in the price of capital relative to the price of financial assets simultaneously raises real capital's market value relative to the capital stock's replacement costs and increases the desired stock relative to the actual stock. The relative increase in the desired stock of capital induces an adjustment in the actual stock through new production. In this manner current output and prices of durable goods are affected by the readjustments in the balance sheets and the related price movements set in motion by the injection of base money. The wealth, income, and relative price effects involved in the whole transmission process also tend to raise demand for non-durable goods.

✓ IV. *Monetary Policy*

⌘ There is probably no field of economics in which the writings of economists are so strongly influenced by both current fashions in opinion and current problems of economic policy as the field of monetary policy. In the period immediately after the war, economists writing on monetary policy were generally agreed that monetary expansion was of little use in combatting depression. ✓ Skepticism about the effectiveness of monetary restraint in combatting inflation was less marked, though some took the extreme view that monetary restraint would either prove ineffective or precipitate a collapse. ✓ But it was generally thought that the wartime legacy of a large and widely-held public debt was a major obstacle to the application of monetary restraint, both because it was feared that abandonment of the bond-support program adopted to assist war financing would destroy public confidence in government debt, and because the transfer from the government to the private banking system that would result from an increase in the interest payable on the latter's large holdings of public debt was regarded as undesirable. Economists therefore divided into those who advocated schemes for insulating bank-held government debt from general interest-rate movements, as a means of clearing the way for monetary restraint, and those who argued for an extension of selective credit controls. ✓

⌘ The inflation that accompanied the Korean War forced the termination of the bond-support program, and thereafter monetary policy became the chief instrument for controlling short-run fluctuations. The nonmaterialization of the disastrous consequences that some had predicted would follow the termination of the bond-support program, together with the development of the availability doctrine (which enlisted liquidity preference on the side of monetary policy and made

a widely-held public debt a help rather than a hindrance) strengthened confidence in the power of monetary restraint to control inflation, though the availability doctrine also provided ammunition to advocates of selective controls by depicting monetary policy as achieving its results through irrational and discriminatory mechanisms. (Subsequent experience, together with empirical and theoretical research, has fairly conclusively disposed of the availability doctrine's most appealing feature—the proposition that the central bank can produce large reductions in private spending by means of small increases in interest rates—and research has tended to refute the contention that monetary policy operates discriminatorily. Nevertheless, the availability doctrine has left its mark on the field, inasmuch as the majority of monetary economists would probably explain how monetary policy influences the economy by reference to its effects on the availability and cost of credit, with the stress on availability. Trust in the power of monetary restraint to control inflation has been further reduced by the coexistence of rising prices and higher average unemployment in the late 1950's, and the associated revival and elaboration of cost-push theories of inflation. On the other hand, experience of monetary policy in three mild business cycles has revived confidence in the efficacy of monetary expansion in combatting recessions and dispelled the belief that monetary restraint in a boom will do either nothing or far too much. In fact, the wheel has come full circle, and prevailing opinion has returned to the characteristic 1920's view that monetary policy is probably more effective in checking deflation than in checking inflation.³⁰)

(Changing fashions in prevailing opinion apart, the revival of monetary policy as a major branch of economic policy has stimulated much controversy, thought, and research on all aspects of monetary policy.) In addition, the legacy of war debt and the increased size and frequency of government debt operations that it has entailed, together with the difficulties created for the Treasury by "bills only" and other Federal Reserve and governmental policies, has brought the whole subject of debt management within the purview of monetary economists as a special form of open-market operations. It is neither possible nor worthwhile to attempt to survey all the issues discussed in this voluminous literature: the Report of the Commission on Money and Credit [128] contains a consensus of informed professional opin-

³⁰ This account refers, of course, to developments in the United States (compare Paul Samuelson [57, pp. 263-69]). A parallel evolution of opinion has occurred in other countries, though in Britain prevailing opinion, as reflected notably in the Radcliffe Report [127, Ch. 6], has remained skeptical of the efficacy and usefulness of monetary policy; this difference in prevailing opinion is partly responsible for the generally critical reception of the Report by U.S. commentators. Limitations of space make it necessary to confine this section to developments in the United States.

ion on most of them, the usefulness of which is much reduced by the absence of documentation of empirical statements and precise references to conflicting points of view; Friedman's *A Program for Monetary Stability* [34] discusses many of the issues within a consistent theoretical framework; and a 1960 *Review of Economics and Statistics* symposium [57] assembles the views of a variety of monetary specialists. The remainder of this part will instead concentrate on what seem to be the significant developments in three areas: the objectives of economic policy and the instrumental role of monetary policy; the means by which monetary policy influences the economy and their effectiveness; and the adequacy of the tools of monetary policy.

A. The Objectives and Instrumental Role of Monetary Policy

In pre-Keynesian days, monetary policy was the single established instrument of aggregative economic policy, and price stability was its established objective. The Keynesian revolution introduced an alternative instrument, fiscal policy, and a second objective, maintenance of full employment (now more commonly described as economic stability), which might conflict with the objective of price stability. Since the war, debt management has been added almost universally to the list of instruments; and since the middle 1950's many economists have added a third item—adequately rapid economic growth—to the list of objectives. In recent years the balance-of-payments problem has been forcing the admission of a fourth objective—international balance—and may eventually establish a fourth instrument—foreign economic policy.

Recognition of several objectives of economic policy introduces the possibility of a conflict of objectives requiring resolution by a compromise. This possibility and its implications have been more clearly recognized elsewhere (for example by the Radcliffe Committee [127, pp. 17-18]), than in the United States, where there has been a tendency to evade the issue by denying the possibility of conflict³¹ or by insisting that conflicts be eliminated by some other means than sacrifice of the achievement of any of the objectives.³² Where a conflict of objectives has been clearly recognized—notably in the criticisms

³¹ This can always be done by giving priority to one objective and defining the others in terms that implicitly impose consistency with the favored objective; an example is the concept of "sustainable economic growth" promulgated by the Federal Reserve System.

³² One example of this type of evasion is the affirmation that balance-of-payments difficulties should not be allowed to hinder the achievement of domestic policy, an affirmation rarely accompanied by specification of any obviously efficacious solution to these difficulties. Another is the expression of trust that policies designed to increase the competitiveness and efficiency of the economy will eliminate the possibility of conflict between high employment, price stability, and adequate growth. Both are contained in the Report of the Commission on Money and Credit [128, p. 227, p. 45].

directed at the anti-inflationary emphasis of Federal Reserve policy in 1957-60—the arguments about alternative compromises have been qualitative and nonrigorous; rigorous theoretical exploration and quantitative assessment of the costs and benefits of alternative compromises between conflicting policy objectives remain to be undertaken.

The availability of alternative policy instruments introduces the question of their absolute and comparative effectiveness; research on this range of problems has been undertaken by a number of economists, but has not progressed far towards an accepted body of knowledge. As already mentioned, monetary policy since 1951 has resumed a large part of the responsibility for short-run economic stabilization—a consequence of both the inadaptability of the budgetary process to the requirements of a flexible fiscal policy and the domination of the budget by other objectives of national policy than stabilization. Reliance on monetary policy for this purpose has raised the question of how effectively the task is likely to be performed. The argument for using monetary policy is usually expressed in terms of the “flexibility” of monetary policy, by which is often meant no more than that monetary policy can be changed quickly. But the real issues are whether the monetary authorities are likely to take appropriate action at the right time, and whether the effects of monetary action on the economy occur soon enough and reliably enough to have a significant stabilizing effect.

As to the first question, there is general agreement that the Federal Reserve has committed errors in the timing, extent and duration of policy changes. Most economists seem inclined to trust the System to improve its performance with experience and the benefit of their criticism. Some, however, are so distrustful of discretionary authority in principle, or so skeptical of the feasibility of effective stabilization by monetary means, as to advocate that the Federal Reserve should not attempt short-run stabilization, but should confine itself (or be confined) to expanding the money supply at a steady rate appropriate to the growth of the economy (for variants of this proposal, see Friedman [34, pp. 84-99], Angell [57, pp. 247-52], and Shaw [106]). The proposal to substitute a monetary rule for the discretion of the monetary authority is not of course new—Henry Simons’ classic statement of the case for it [108] appeared in the 1930’s—but the definition of the rule in terms of the rate of monetary expansion rather than stability of a price index reflects both the modern concern with growth and a more sophisticated understanding of the stabilization problem.

Whether such a rule would have produced better results than the policy actually followed in the past is a difficult matter to test. Fried-

man [34, pp. 95-98] discusses the difficulties and describes some abortive tests that tend to favor his (4 per cent annual increase) rule. Martin Bronfenbrenner has devised a more elaborate series of tests of alternative rules, including discretionary policy; his results for annual data 1901-1958 (excluding the Second World War) [11] show that a 3 per cent annual increase rule comes closest to the "ideal pattern" defined by price stability, though his subsequent tests on quarterly data from 1947 on [12] suggest the superiority of a "lag rule" relating changes in the money supply to prior changes in the labor force, productivity and velocity. These tests are subject to statistical and theoretical objections, but they open up an interesting new line of research. In the absence of a definitely specified standard of comparison, discussions of the appropriateness of the central bank's monetary policy tend to fall back on textual criticism of its explanation of its actions or the exercise of personal judgment about what policy should have been (see, for example, the contributions of Weintraub, Samuelson, and Fellner to [57]).

The question of the extent of the stabilizing effect that monetary action may be expected to achieve was first raised, at the formal theoretical level, by Friedman [39], who argued that policies intended to stabilize the economy might well have destabilizing effects because of the lags involved in their operation. Subsequent work and discussion on this aspect of monetary policy has concentrated on the length and variability of the lag in the effect of monetary policy, and has become enmeshed in intricate arguments about the proper way of measuring the lag. Two alternative approaches to the measurement of the lag have been employed, direct estimate and statistical inference. The outstanding example of the first is Thomas Mayer's study of the inflexibility of monetary policy [79]. Mayer estimates the lag in the reaction of investment expenditure and consumer credit outstanding to monetary policy changes, sector by sector, and, taking into account lags in monetary-policy changes and the multiplier process, concludes that monetary policy operates on the economy much too slowly for its effects to be quickly reversed; from a computation of the effect that an optimally-timed monetary policy would have had on the stability of industrial production over six business cycles, he concludes that monetary policy is too inflexible to reduce the fluctuation of industrial production by more than about 5 to 10 per cent on the average [79, p. 374]. W. H. White [125] has since argued that Mayer seriously overestimates the average lag, and that the correct estimate would provide almost ideal conditions for effective anticyclical policy; White also remarks that Mayer's results do not show the destabilizing effects indicated as possible by Friedman's analysis.

Statistical inference is the basis of Friedman's contention that

monetary policy operates with a long and variable lag, a contention which figures largely in his opposition to discretionary monetary policy. Friedman's preliminary references to his results, which are yet to be published in full [42], made it appear that this contention rested mostly on a comparison of turning points in the rate of change of the money stock with turning points in National Bureau reference cycles (that is, in the level of activity); this comparison automatically yields a lag a quarter of a cycle longer than does a comparison of turning points in the level of the money stock with reference-cycle turning points, the comparison that Friedman's critics regard as the proper one to make. In reply to criticisms by J. M. Culbertson [26], Friedman has produced a lengthy defense of his measure of the lag, together with other supporting evidence [40]. This defense indicates that the measurement of the lag raises much more subtle and fundamental theoretical and methodological issues than appear at first sight; but the majority of monetary economists competent to judge is likely to agree with Culbertson [28] in finding Friedman's arguments unpersuasive.

Statistical inference is also employed in the study of lags in fiscal and monetary policy conducted for the Commission on Money and Credit by Brown, Solow, Ando and Kareken [14]. These authors claim that Friedman's comparison of turning points in the rate of change of the money stock with turning points in the level of activity involves a methodological *non sequitur*, and find from a comparison of turning points in the rates of change of money with the rate of change of aggregate output that the money stock and aggregate output move roughly simultaneously over the cycle. Their own work attempts to estimate the lag between the indication of a need for a change in monetary policy and the effect of the resulting change in policy on output, and finds that a substantial stabilizing effect is achieved within six to nine months. They also find that fiscal policy operating on disposable income is a more powerful stabilizer, achieving as much as half of its effect within six months.

This research on the lag in effect of monetary policy has been orientated towards determining the efficacy of monetary policy as a stabilizer, on the assumption that monetary policy is decided with reference to contemporaneous economic conditions. Little if any research has been devoted to the more ambitious task of designing optimal systems of changing monetary policy in response to movements of relevant economic indicators. A. W. Phillips [95] and more recently W. J. Baumol [8] have shown that what seem like sensible procedures for changing a policy variable in response to changing conditions may well aggravate instability; Phillips has applied the theory

and concepts of control systems to the analysis of the effects of alternative operating rules of stabilization policy.

B. The Effectiveness of Monetary Policy

To turn from the instrumental role of monetary policy to the related but broader questions of how monetary action influences the economy, and how effectively, the prevailing tendency has been to approach these questions by analyzing how monetary policy, and particularly open-market operations, affect the spending decisions of particular sectors of the economy. This formulation of the problem is a natural corollary of Keynesian theory, and the evolution of the analysis since the war has closely reflected the evolution of monetary theory, though with a perceptible lag; but the analysis has also been strongly influenced by the availability doctrine. That doctrine, the formulation of which was largely the work of Robert Roosa [99], emerged in the later years of the bond-support program as a solution to the conflict between the belief that a large widely-held public debt obliged the central bank to confine interest-rate movements to narrow limits and the belief that large interest-rate changes were necessary to obtain significant effects on spending.

The doctrine comprised two central propositions. The first was that widespread holding of public debt, particularly by financial institutions and corporations, facilitates monetary control by transmitting the influence of interest-rate changes effected by open-market operations throughout the economy. The second was that small interest-rate changes could, by generating or dispelling uncertainty about future rates and by inflicting or eliminating capital losses that institutions were unwilling to realize by actual sales ("the pinning-in effect"), achieve significant effects on spending even if the demands of spenders for credit were interest-inelastic—these effects being achieved by influencing the willingness of lenders to lend or, put another way, by influencing the availability of credit to borrowers by altering the terms of credit and the degree of credit rationing. The second proposition has turned out on subsequent investigation to depend on incorrect empirical assumptions about institutional behavior, particularly with respect to "the pinning-in effect" (see Warren Smith [112]) and on a doubtful asymmetry between the reactions of lender and borrower expectations to interest-rate changes (see Dennis Robertson [97]), as well as to involve some logical inconsistencies (see John Kareken [64], and for a theoretical defense of the availability doctrine, Ira Scott [103]). Nevertheless, the doctrine and discussion of it have helped to popularize the concept of "availability of credit" as one of the main variables on which monetary policy operates.

"Availability" actually comprises a number of disparate elements—the liquidity of potential lenders' and spenders' assets, the terms on which lenders will extend or borrowers can obtain credit, and the degree to which credit is rationed among eligible borrowers (see Kareken [64]). Emphasis on these factors as influences on spending has provided new arguments for those who favor selective credit controls—specific arguments for controls where the terms of credit rather than the cost of credit seem the effective determinant of spending decisions, as in the case of instalment credit, and a general defensive argument based on the discriminatory character of credit rationing. The most powerful attack on the discriminatory character of allegedly general methods of economic control has come from J. K. Galbraith [45], who has maintained that the use of monetary and fiscal policy has favored the monopolistic at the expense of the competitive sectors of the economy to an extent comparable to repeal of the antitrust laws. Others have maintained that monetary restraint discriminates against small business. Empirical studies by Bach and Huizenga [6] and Allen Meltzer [82] show that this is not true of bank credit; Meltzer's study finds that while small firms have greater difficulty in obtaining non-bank credit in tight periods than large firms, this discrimination tends to be offset by extension of trade credit from large firms to small.

The emphasis on the availability of credit as a determinant of expenditure has led to a critical re-examination of the business-attitude survey findings that formerly were used as evidence that business investment is insensitive to monetary policy. In addition, monetary theorists have tended to raise their estimates of the sensitivity of business investment to changes in the cost of credit. These reassessments have been based on the opinion that investors' expected profits are more finely and rationally calculated than used to be thought, rather than on any impressive new empirical evidence of such sensitivity. The most definite new empirical evidence there is confirms the long-time theoretically established sensitivity of residential construction to interest-rate changes, and even this sensitivity has been attributed in part to the influence of ceiling rates on federally-guaranteed mortgages on the willingness of institutional lenders to lend on such mortgages [128, p. 51]. The failure of empirical research to disclose such sensitivity may, as Brunner has suggested [18, p. 613], be the consequence of too simple a theoretical approach, the attempt to relate a flow of expenditure on assets to the cost of credit without adequate recognition of the range of alternative assets or the complexities of stock-adjustment processes. The new approach to monetary dynamics described in the previous part suggests that a more sophisticated

theory of real investment is necessary for successful empirical work; on the other hand, some of the empirical work described in Part II suggests that better results might be achieved by working with changes in the quantity of money than by attempting to determine the influence of changes in interest rates on particular categories of spending.

The discussion of the effectiveness of monetary policy just described has been concerned with monetary policy operating in a given institutional environment. (Since the middle 1950's a new debate has been opened up, concerned with the fact that traditional methods of monetary control are primarily directed at commercial bank credit, and the possibility that institutional change stimulated by monetary restriction may reduce the effectiveness of traditional techniques of monetary control. The main debate has been concerned with Gurley and Shaw's contention [50, pp. 537-38] that the growth of financial intermediaries, prompted in part by the competitive handicaps imposed on commercial banks for purposes of monetary control, progressively provides close substitutes for money the presence of which weakens the grip of monetary policy on the economy; and with their suggestion that the controlling powers of the central bank should be extended beyond the commercial banks to other financial institutions.³³ The debate has ranged over a wide territory, including such matters as whether existing controls over commercial banks are really discriminatory, given that banks enjoy the privilege of creating money (Aschheim [3] and Shelby [107]) and whether imposition of credit controls on financial intermediaries would in fact improve the effectiveness of monetary policy or the competitive position of the banks (David Alhadeff [1]). From the point of view of monetary policy, the central issue is not whether financial development leads to a secular decline in the demand for money—by itself, this would increase the leverage of monetary policy (Shelby [107]) and could readily be assimilated by the monetary authorities ([128, pp. 80-81] and Axilrod [5])—but whether the liabilities of financial intermediaries are such close substitutes for money that monetary restriction is substantially offset through substitution for bank deposits of other financial claims backed by only a small fractional reserve of money—in short, whether financial intermediaries substantially increase the interest-elasticity of demand for money. This is an empirical question; and the empirical evidence

³³ A related but different argument has been advanced by Hyman Minsky [85], to the effect that monetary restriction stimulates financial innovations that progressively reduce the demand for money, increase the velocity of circulation, and threaten to make the money market unstable; Minsky recommends extension of the lender-of-last-resort function to the whole market and not merely the commercial banks. Arguments similar to those of Gurley and Shaw and Minsky may be found in Smith [112].

so far is that shifts by the public from money into thrift assets in periods of monetary restraint have not had a significant influence on velocity ([128, pp. 78-80]; see also Smith [110]).

C. The Adequacy of the Tools of Monetary Policy

The revival of monetary policy as an instrument of short-run stabilization has provoked a great deal of discussion not only of the use and effectiveness of monetary policy, but also of the use and efficiency of the Federal Reserve's traditional instruments of monetary control—open-market operations, rediscount rates, and reserve requirements. Controversy about open-market operations has centered on the "bills only" policy—the policy of conducting open-market operations in Treasury bills only, adopted by the Federal Reserve in 1953, modified later to "bills usually," and abandoned in 1961. Both the availability doctrine and the assets approach to the theory of interest rates imply that the central bank can obtain differential effects on credit conditions according to the maturity of government debt in which it chooses to conduct open-market operations, and can alter the structure of interest rates by switching between short and long maturities. The bills-only policy therefore appeared to most academic economists as an undesirable renunciation by the central bank of an important technique of monetary control, and the reason given for it—the desire to improve the "depth, breadth and resiliency" of the government bond market by eliminating arbitrary central bank intervention in it—as a shallow excuse masking the unwillingness of the Federal Reserve to risk unpopularity with the financial community by overtly subjecting it to capital losses. The surrender of power entailed in bills-only was probably greatly exaggerated by many of its opponents: Winfield Riefler [96] has pointed out that the central bank's choice of securities only contributes about one-eighth of the total effect of its open-market operations, the remaining seven-eighths being determined by the asset choices of the banks whose reserves are altered by the operations; and has produced some evidence that substantial changes in the maturity composition of the public debt have had little effect on the rate structure. On the other side of the argument, Dudley Luckett [76] has shown that the empirical evidence fails to indicate any improvement in "depth, breadth and resiliency" since bills-only was adopted.

While much of the discussion of bills-only has been concerned exclusively with Federal Reserve policy, the fundamental issue involved was the division of responsibility for the maturity composition of government debt held by the public between the Federal Reserve and the Treasury. Bills-only assigned this responsibility, and the associated

responsibility for smoothing the impact of debt-management operations on the market, to the Treasury. One school of thought, represented for example by A. G. Hart [57, pp. 257-58], has maintained strongly that this is an inappropriate division of responsibility, since the Federal Reserve has both the powers and the continual contact with the market required for the purpose and the Treasury has not. (The limited ability of the Treasury to conduct open-market operations has been demonstrated by Deane Carson's study [21] of debt management after the adoption of bills-only.) Others have seen the source of the trouble in the Treasury's debt management practices, particularly the practice of issuing debt in large blocks at irregular intervals, at fixed prices and with maturities "tailored" to market requirements. Carson [21] and Friedman [34, Ch. 3] have proposed similar schemes for replacing present practice by a system of auctioning long-term government debt issues; Culbertson [25] and Friedman [34, Ch. 3] have propounded plans for regularizing the timing and composition of debt issues to reduce the market disturbance of government financing. The difficulties the Treasury has experienced with debt management in the postwar period, in consequence not only of bills-only but of other developments adverse to easy Treasury financing,³⁴ have led many economists to become skeptical of the practicability of a countercyclical debt-management program. Such a program, which would involve issuing long-term debt in booms and short-term debt in depressions, would in any case have a countercyclical influence only insofar as the interest-rate structure is sensitive to change in the composition of the debt, and this sensitivity seems to be too small to yield important stabilizing effects (see Riefler [96] and Meiselman [81]).

Though the growth of the public debt has definitely established open-market operations as the chief instrument of day-to-day monetary control, the revival of monetary policy has been accompanied by a revival of rediscounting and the use of rediscount rates as a control instrument. Controversy over rediscount policy has mainly been concerned with whether rediscount policy is a useful auxiliary instrument of control, or whether the possibility of rediscounting creates an unnecessary and troublesome loophole in the control over member banks afforded by reserve requirements and open-market operations. It can be argued (see Friedman [34, pp. 34-35]) that rediscount rates are a treacherous control instrument, since their restrictiveness depends on their relationship with shifting market rates of interest, and that the growth of bank holdings of public debt and the postwar development of

³⁴ For a comprehensive survey of these developments see Erwin Miller [84].

the federal funds market make it unnecessary for the Federal Reserve to continue to perform the function of lender of last resort for its members.³⁵ There has also been some argument about whether control of the rediscounting privilege gives the Federal Reserve undesirable arbitrary authority over member banks.

Apart from the debate concerning the desirability of rediscounting, a number of writers have criticized the asymmetry of the present reserve-requirement and rediscount-rate system, under which member banks receive no interest on reserves or excess reserves but pay a penalty rate on reserves borrowed to meet deficiencies, and have proposed payment of interest on reserves or excess reserves. Tobin, for example [57, pp. 276-79], has recommended payment of interest at the discount rate on excess reserves, and coupled this with the recommendation to terminate the prohibition of demand-deposit interest and the ceilings on time- and savings-deposit interest, arguing that the justification for intervention in the fixing of deposit rates—to protect depositors by preventing excess competition among banks—has been removed by federal deposit insurance.³⁶

The power to change reserve requirements gives the central bank a method of changing the quantity of bank deposits alternative to open-market operations. The chief differences between the two methods³⁷ are, first, that reserve-requirement changes, being discontinuous, are apt to have disturbing effects on securities markets requiring auxiliary open-market operations; and second, that credit expansion by open-market purchases is less costly for the government and less profitable for the banks than credit expansion by reduction of reserve requirements (and vice versa). The discontinuity and disturbing effects of reserve-requirement changes, dramatically exemplified by their misuse in 1936-37 (see Brunner [15]), have led most economists to believe that they should be used sparingly if at all, especially in restraining credit expansion. The differential effects of the two methods of control on governmental interest costs and bank profits have been the focus of controversy over the policy of lowering reserve requirements fol-

³⁵ The controversy has aroused some interest in the Canadian innovation of setting the discount rate at a fixed margin above the weekly average tender rate on Treasury bills. In England, where the rediscount rate is the chief instrument of monetary policy, recognition of the loophole in monetary control afforded by rediscounting has led to the promulgation of the theory that the liquidity ratio of the commercial banks and the supply of bills, rather than the cash ratio and the quantity of central bank deposits, determine the amount of commercial bank deposits.

³⁶ The fact that this justification was fallacious to begin with has not prevented the Commission on Money and Credit from endorsing the continuation of control of these rates [128, pp. 167-68].

³⁷ For a fuller analysis, see Aschheim [4, Ch. 2].

lowed by the Federal Reserve since 1951. In the course of time the balance of the argument has tilted in favor of reduction of reserve requirements, as the postwar sentiment against high bank profits derived from interest on the public debt has given way to the more recent fear that banks are unduly handicapped by reserve requirements and interest ceilings on deposits in competing with other financial intermediaries.

The controversy has raised the more general issue of how the secular growth of the money supply should be provided for. George Tolley, who first raised this issue [118], has shown that the choice between open-market operations and reserve-requirement variation involves some intricate theoretical issues, since in addition to its implications for debt management and the ease of government financing this choice influences the efficiency of allocation of resources to the provision of the supply of deposit money.

Some attention has also been given to the efficiency of the present system of reserve requirements as an instrument of monetary control. Frank Norton and Neil Jacoby [88] have revived the 1930's Federal Reserve proposal to relate required reserve ratios to deposit turnover rates as a means of introducing an automatic offset to changes in the velocity of circulation. The preponderance of professional opinion, however, seems opposed to any system of reserve requirements that discriminates between banks or affects their profits differentially, and in favor of the removal of inequities among banks by the standardization of reserve requirements.

V. Concluding Remarks

The main impression that emerges from this survey of monetary theory and policy is not only that the field has been extremely active, especially in the past few years, but that it has been on the move towards interesting and important new developments. To summarize what is already a summary is a difficult task, and prediction of the direction of future scientific progress is a risky business; but in the literature surveyed in the preceding sections, two broad trends are evident. One is the trend towards the formulation of monetary theory as a part of capital theory, described in Part II (and implicitly in Part I). As mentioned in Part III, this trend has only just begun to manifest itself in the formulation of monetary dynamics. More important, almost nothing has yet been done to break monetary theory loose from the mould of short-run equilibrium analysis, conducted in abstraction from the process of growth and accumulation, and to integrate it with the rapidly developing theoretical literature on eco-

nomie growth (important exceptions are the models of Tobin [113] and Enthoven [52, App.]). The other trend is that toward econometric testing and measurement of monetary relationships. As is evident from Part IV, econometric methods have barely begun to be applied to the study of relationships relevant to the management of monetary policy.

CZECHOSLOVAK INDUSTRIAL GROWTH: 1948-1959

By GEORGE J. STALLER*

The importance for the Western world of the industrial growth of the planned economies is today generally accepted. We are fortunate to have at our disposal several independent estimates of the Soviet industrial expansion over the last thirty years.¹ The intense interest in the industrial might of the Soviet Union has not as yet spread to the area of Eastern Europe² which should be considered an integral part of the Soviet industrial empire. This is somewhat surprising in view of the fact that the four major industrial nations of the East European bloc (Czechoslovakia, East Germany, Hungary, and Poland) produce today about one-third of the Soviet output of basic industrial products.³

The purpose of this paper is to present results of the study of one country belonging to the bloc. Czechoslovakia was selected for two reasons. First, together with East Germany, it is industrially the most advanced country of the bloc. Second, the country was industrialized at the time the Communist Party took full control of the government. Thus Czechoslovakia offers an interesting example of a developed industrial complex to which Soviet-type planning was applied *ex post*.

Industrial production facilities became property of the Czechoslovak state in two waves of nationalization. The first came in the fall of 1945 in the form of two presidential decrees which nationalized completely such basic industries as mining and power-generating; a loosely defined criterion of which enterprises were most important for the nation's economy led to varying degrees of nationalization of other industries [50]. The second wave of nationalization came after the Communist Party assumed full control of the government in February 1948. Two nationalization laws, passed in April 1948 [60], abolished

* The author is assistant professor of economics at Cornell University. He wishes to thank M. Gardner Clark, Alfred E. Kahn, Boris P. Pesek, and Maurice C. Ernst for helpful comments. The final version of the paper was written with financial assistance of the Rockefeller Foundation.

¹ For the most recent measure as well as for references to previous work, see [10].

² One notable exception is Stolper's book on the East German economy [39].

³ In 1959, the combined output of these four countries represented the following percentages of Soviet output: electric power, 34.9; hard coal, 35.5; brown coal, 212.4; crude steel, 28.8; cement, 40.5; sulphuric acid, 38.6 [36, pp. 529-35].

for all practical purposes the private sector of Czechoslovak industry.⁴ The future of crafts as a form for the organization of manufacturing activity was decided in the same year; crafts establishments were rapidly transformed and incorporated in industrial enterprises.⁵ Thus the institutional framework within which industry was to operate was established at the beginning of the period under consideration.

The plan of the paper is as follows: The first section discusses the official production index and introduces a new measure of Czechoslovak industrial growth.⁶ The second section describes the changes in industrial structure, the growth of output, and the means to achieve it; the section also compares the growth of Czechoslovak industry with that of its Communist and Western neighbors. The concluding section dwells briefly on the past and the future of the nation's industry.

I. Industrial Production Indexes

According to the official index, which uses the year 1948 as the base period, Czechoslovak industrial production increased 50 per cent by 1951, doubled by 1954, tripled by 1958, and stood at 333 per cent of the 1948 level by 1959 [36, p. 137]. The official measure is a Soviet-type index of gross value of production ascertained at the enterprise level. Two sets of wholesale prices have been used in the calculation: January 1, 1953 prices for the period 1948 to 1955, and July 1, 1954 prices for the ensuing period. The Soviet definition of industrial production and the methods of measuring its growth were fully adopted in the middle of 1952 together with the Soviet planning techniques. The State Statistical Office constructed the index for the first half of the period by retrospective investigation.

The objections that have been raised by Western scholars to the Soviet industrial production index apply equally to the Czechoslovak index, and have in fact been publicly made in Czechoslovakia: faulty procedures in pricing new products or new models of old products [47, p. 304] [42, pp. 702-3] [20, p. 135], the "statistical discovery" of previously unrecorded production, the broadened concept of industrial production [48, p. 286] [3, p. 195] [52], and the changes in vertical integration which affected the magnitude of the gross value of production [1, p. 391] [12, pp. 446-47]. The retrospective investiga-

⁴At the end of 1948, the industrial private sector employed 48.3 thousand people compared to the 1,326 thousand employed in the nationalized sector [8, p. 186].

⁵The number of persons in crafts amounted to 458.9 thousand at the end of 1948. Within two years, employment dropped by 50 per cent and declined further to about 10 per cent of the 1948 level by 1952 [34, p. 180].

⁶A more detailed discussion of the new measure and an evaluation of its reliability is relegated to the appendix.

tion which covered the period 1948 to 1952 raises additional doubts about the reliability of the official index. The definition of gross value of production is quite complex; much of the data necessary for the calculation was simply not available prior to 1952 and had to be estimated [18, p. 226] [43, p. 224].

Severe criticism of the index appeared in Czechoslovak economic literature within two years of its introduction. In contrast to the discussion of other topics, such as wholesale price formation, which was characterized by wide diversity of opinion, there was a consensus among all contributors to the discussion that the official index suffered by an upward bias; not a voice was raised in its defense.⁷ No estimate of the bias was published in Czechoslovakia although it appears that a net value index of industrial production was computed by the State Statistical Office [2, p. 54]. Fortunately, enough data are available on Czechoslovak industry to make possible an independent calculation of a new index of Czechoslovak industrial output which employs the concepts and methodology of Western statistical practice [44].

A. The Weighting System

The year 1948 was selected as both the weight base and the comparison base period. The amount of information on the structure of "industry proper" and on "manufacturing crafts"⁸ in that year exceeds that of any other year of the postwar period. The base-year selection can also be supported by other considerations. The worst shortages caused by the war had been overcome and the reconstruction and conversion to civilian production completed. Moreover, both the factor and the product markets were at this time reasonably similar to Western-type markets, more so than during any other time after the war. The selection of this particular weight base year should not greatly influence the measured rate of growth; the time period covered by the new index is relatively short, and Czechoslovak industry

⁷ For a summary of the discussion, see [58].

⁸ Czechoslovak industrial activity was organized after the Second World War in these two economic sectors. The delineation of the sectors was accomplished shortly before the war: no attempt was made at the time to classify the producing units according to accepted economic criteria—such as the extent of the market supplied by the producing unit, its use of mechanical power, or the number of employees—which usually distinguish these two spheres of economic activity. As a result, certain lines of manufacturing, for example, production of paper mills, glassware, or printing establishments, were all included in industry proper though in many instances the production units had less than five employees. On the other hand, certain large establishments which employed several hundred workers, especially in the woodworking, textiles, and food processing lines, were classified as crafts [17, pp. 336-37]. Manufacturing crafts represented in 1948 the following percentages of the combined value added of the two sectors: metalworking, 9.0; leather and rubber, 14.2; woodworking, 14.0; textiles and clothing, 16.9; provisions, 20.9; stone, clay, and ceramics, 1.7. See Table 1.

was well advanced in 1948. Consequently, no strong correlation between changes in outputs and prices over time is to be expected.⁹

Three sets of weights have been successively employed in the calculation of the new index: value-added weights for individual industries; compensation of employees for industrial sectors and for product groups; and wholesale prices for individual commodities within product groups.

B. Indicators of Output

Different approaches had to be used for measuring the output of crafts and of industry proper since physical output data are not available for the former. It is known, however, that production of consumer goods in the crafts sector, which was widespread in 1948, was rapidly restricted in subsequent years [38, p. 393]. In calculating the new index of output, we could either leave out completely those industrial sectors which absorbed the crafts and assume that the output of these sectors moved parallel to the output of the remaining sectors and industries, or we could measure the movement of crafts' output by employment. The second method was chosen.

The growth of output of industry proper has been measured by quantities expressed in physical units. The average number of civilian products included in the new index for the period as a whole is over 200, the period between 1948 and 1953 being represented by about 150 products and the remaining period by about 300 products. The coverage is better than the numbers indicate: many of the series employed are aggregates. All products for which weights could be found or estimated have been included in the new index of output; no judgment has been exercised as to the "representativeness" of the series.

Only one important adjustment was made to take account of the impact of the Korean War on production in the machinery industry [29, p. 26]. Production in most industrial sectors within the machinery industry shows an uninterrupted growth for the whole period under consideration. However, production in the vehicles sector¹⁰ shows a decline between 1951 and 1954 and a sharp rise thereafter. It is likely that this decrease in output of civilian products was caused by a shift to armaments production. The growth of output of this sector between 1951 and 1954 has been interpolated by an unweighted production index of castings, forgings, rolled products, and hot formed products.

Table 1 presents the results of these computations, showing the index

⁹ The influence of weight base period on the measured rate of growth is discussed in [6, pp. 47-56].

¹⁰ Represented by passenger cars, trucks, busses, trolleys, tractors, and motorcycles.

TABLE 1. THE VALUE-ADDED INDEX OF OUTPUT, 1948 TO 1959
1948 = 100

Industries	Relative Weights	1948	1949	1950	1951	1952	1953	1954	1955	1956	1957	1958	1959	1948-1959*

of total output, broken down among twelve industries, as well as between the producer and consumer goods industries.¹¹

II. *Patterns of Industrial Growth*

The new index of industrial output will be used to answer two broad questions: what happened to the Czechoslovak industrial output and structure, and how did it happen. Moreover, the time pattern of growth over the twelve-year period under consideration will be analyzed, and a comparison with growth of Czechoslovakia's Communist and non-Communist neighbors will be made.

A. *Output Growth and Structural Change*

The expansion of manufacturing output was supported by the growth of the country's fuel base, with coal supplying practically all primary power.¹² Extraction of hard and brown coal increased between 1948 and 1959 by 42 and 126 per cent respectively, with nearly all of the increase coming from existing mines. This growth was achieved through rapid mechanization of both underground and surface mining and by continuous supply of shock-brigade workers temporarily drawn from other occupations [49, p. 72]. However, both these factors led to serious deterioration in the calorific content of coal [19, pp. 787-88]. About one-third of the extracted coal was used in thermal stations for generation of electric power; hydropower supplied about 10 per cent of the total in 1959. Seventy-three per cent of all generated electric power was used in industry, the percentage varying between 81 per cent in 1948 and 71 per cent in 1959.

As Table 1 shows, chemicals and machinery and metalworking industries led the advance by a wide margin. The fastest growing part of the chemicals industry was the pharmaceuticals sector, which was a new field in 1948; output of general chemical works increased by 2.5 times. The growth of machinery and metalworking industry was made possible by the steady expansion of steel production. By 1959, Czechoslovakia produced 452 kilograms of steel per capita, which put her quite close to U. S. production of 477 kilograms and well above Soviet production of 285 kilograms [36, p. 533]. Output of rolled products grew at a steady rate of 7.7 per cent per annum, output of castings and forgings at 10.2 per cent per annum. Compared to these industries,

¹¹ Following the 1948 official classification, producer goods industries are mining, power generating, machinery and metalworking, rubber, and construction materials. Consumer goods industries are textiles, clothing, shoes and leather, glass, woodworking, paper, printing, and provisions.

¹² Between 1952 and 1957, for example, coal accounted for 92.7 per cent of total domestic sources of power [35, p. 138].

most consumer goods industries, such as textiles, glass, ceramics, or shoes and leather, for which Czechoslovakia was known before the war, lagged behind. For the period as a whole, the consumer goods industries registered a growth rate well below the producer goods industries (6.1 as against 10.1 per cent per annum).

Table 2 shows the resulting changes in industrial structure for producer and consumer goods taken as groups, and for leading industries. All three measures (value added, manual workers employment, and fixed capital) clearly indicate the rapid shift toward the producer goods industries, with the machinery and metalworking industry reaching a prominent place by 1959.

B. Inputs and the Output-Input Ratios

Table 3 presents estimates of major industrial inputs. The growth of total employment was made possible in part by the sharp rise in the

number of women employed, from the already high level of 27.5 per cent of the labor force in 1948 to 33.3 per cent in 1953 and to 36.7 per cent at the end of the period [36, p. 90]. The expansion was achieved by the use of both carrot and stick. The increasing weight of the stick was clearly reflected in the progressively stricter labor legislation, beginning in 1947 with the broad general law "Concerning Some Measures to Ensure the National Draft of Labor" [59] and culminating in the 1953 passage of the law "Concerning Measures against Labor Turnover and Absenteeism" which in its Draconian character can be

compared with Soviet labor legislation of the 'thirties and early 'forties [56].¹³

On the positive side of inducements, wages and salaries have been increasing steadily. If these official statistics can be trusted, industrial employees' compensation increased faster than their productivity, especially during the early 'fifties [51, p. 543]. An important part of the inflationary pressures prevailing at that time apparently originated in industry and can be partially explained by the wage policy. Though the compensation of manual workers increased considerably faster than that of technical and white collar staff, employment of nonmanual workers grew faster than employment of manual workers.¹⁴ Most of the divergence occurred during the early years of the period and can probably be explained by the creation of the industrial planning and control mechanism.

The capital series is based on statistics of undepreciated value of fixed assets. For measuring the input of capital, the series is adjusted upward by the gradually increasing number of second and third shifts. Taking the first shift as equal to 1, the "coefficient of capital utilization," expressed as the ratio of all workers employed to workers on the first shift, was approximately 1.2 in 1948 and 1.36 in 1959.¹⁵

Three indexes present the approximate inputs of materials used by industry: agricultural output, imports of raw materials and semi-finished industrial products, and apparent consumption of energy. The index of agricultural output is weighted by 1948 prices and is all-inclusive, with most products destined for industrial use. Imports of industrial materials composed 60 to 70 per cent of all imports; their growth is expressed in 1953 foreign-trade prices obtained by deflating current values by an implicit price index for total imports. While the index shows a steady climb throughout the years, it hides an important change away from the Western supplier to the supplier within the Communist bloc; imports from the West dropped by 50 per cent by 1953, while imports from the bloc nearly tripled [36, p. 360]. The index of energy consumption is an indicator of availability of energy in

¹³ According to the letter of the law, the director of an enterprise had to report immediately to the State Prosecutor those workers who missed three working days during a calendar year or who left the enterprise without official permission (see Provisions 5 and 9). In this stringent form, the law was repealed five weeks later because of unrest among workers [57], and the emphasis was shifted to economic pressures.

¹⁴ Between 1948 and 1953, average pay of manual workers increased 54 per cent, of technical personnel 26 per cent, and of white collar workers 18 per cent [14, p. 339].

¹⁵ The coefficient for the year 1948 is our estimate based on growth of industrial consumption of electric power and on increases of the machinery and equipment part of the fixed assets between 1952 and 1959; the figure for 1959 is the official figure [36, pp. 41, 155, and 159].

terms of calories for the whole economy rather than for industry alone.¹⁶ Since the percentage of total energy supplies consumed by industry probably increased during the first five-year plan, the index in the table probably understates the growth of energy input into industry between 1948 and 1953.

Table 3 also presents changes in three output-input ratios and in the ratio of fixed capital to employment. The output per worker grew at a rate of 5.6 per cent per annum, output per employee showing a lower growth rate of 4.8 per cent. The output-capital ratio increased by about one-third between 1948 and 1959. The ratio of capital to employment, which remained practically unchanged for the first four years, increased by 25 per cent between 1952 and the end of the period.

C. The Time-Pattern of Growth

The twelve years covered by the new index of output can be divided into three periods as far as the achieved rate of growth is concerned. The rapid expansion during the first two years can best be explained in terms of fuller utilization of existing capacity.¹⁷ While Czechoslovak industry did suffer damage during the war, the capacities of those industries which became focal points of the postwar growth—machinery and chemicals—were larger in 1948 than in 1937, which, incidentally, was still a depression year in Czechoslovakia.

The pace of expansion fell off by one-half during the early 'fifties, which in retrospect appears to be the crucial period of the postwar development. Profound transformations in both organization of industry and in planning techniques which took place at the time were bound to affect the growth rate adversely. Organizational changes were made at all levels, from the production ministry down to individual enterprises, to improve supervision and to separate out from individual enterprises extraneous lines of production inherited from the capitalist period.¹⁸ These changes in organizational structure were paralleled by changes in planning. The method of "specific tasks" planning (i.e. planning of output targets of a limited number of products), which constituted the core of Czechoslovak planning technique for six years, was given up and over-all planning of the Soviet type was adopted in the middle of 1952 [53] as a cure for the mounting difficulties which Czechoslovak planners experienced.

¹⁶ The component series of the index are hard coal, brown coal, lignite, crude oil, natural gas, and hydroenergy, all adjusted for foreign trade. See [25, p. 22] for similar indexes of energy available in the countries belonging to the Organisation for European Economic Co-operation.

¹⁷ For example, the production of electric power increased between 1948 and 1950 by 23.5 per cent while capacity increased by 6.7 per cent [36, p. 160].

¹⁸ For example, the complaint was made in 1952 that the production of notions was organized under the Ministry of Heavy Industry [54, p. 247].

At the same time, both the over-all targets and the product-mix underwent basic changes. The original goals of the first five-year plan initiated in 1949, which had been raised considerably in 1951¹⁹ were probably lowered in 1953. Producer goods industries were given absolute preference over consumer goods industries, which had developed just as rapidly until 1950 but registered practically no growth between 1950 and 1953. The changes in export-import patterns necessitated by the cold war further aggravated the production problems. A monetary reform, executed swiftly in the middle of 1953, repudiated public debt, reduced drastically privately-held assets,²⁰ and abolished the dual price system. The reform caused considerable dissatisfaction and some unrest among industrial workers. The growth at the end of the second period, between 1953 and 1954, was the lowest one registered during the twelve years.

Though the immediate impact of the acceptance of the Soviet planning system and of the monetary reform was negative, both reforms set the stage for the third period of renewed growth. The first reform gave the Czechoslovak planner an established and tested model. The second provided the State with a tight financial rein over the economy. The turbulent transition from an essentially free-enterprise industrial economy to one integrally planned was accomplished. The necessary planning and control mechanism was completed and the all-important experience in planning the aggregate output was acquired. Moreover, the vigorous investment activity initiated during the first five-year plan, fortified by the new policy of completion of existing investment projects rather than embarkation upon new ones, began to show results. The cold war subsided, and Czechoslovakia re-established contacts with countries outside the Soviet bloc²¹ which provided her with necessary materials as well as markets for her industrial products.

D. *East-West Comparisons*

The pitfalls of international comparisons of economic growth are well known: they include such problems as comparable definitions of industrial production; statistical techniques used in measuring growth; and the level of economic activity in the base year. Yet such comparisons do provide the necessary framework in which to view industrial expansion of a country.

¹⁹ The original plan called for industrial production growth by 57 per cent in 1953 (1948 = 100); the revised plan increased this target by 23 per cent, i.e., to 198 per cent of the 1948 level, with heavy industry scheduled to increase to 348 per cent [55].

²⁰ One estimate puts the total repudiation rate between 71 and 76 per cent of all privately held assets [26, p. 381].

²¹ Between 1953 and 1959, exports to the "capitalist" countries increased by 164 per cent and imports by 176 per cent. The corresponding figures for the trade with the bloc were 80 and 85 per cent [36, p. 359].

Table 4 presents the data for four Communist neighbors of Czechoslovakia for which Western-type industrial production indexes have been calculated: the Soviet Union [10], East Germany [39], Hungary [16], and Poland [5]. Two periods are considered: the first spans nearly a decade, the second covers the latter part of the 'fifties. Czechoslovakia registered over the decade the lowest rate of growth in total output, but the range between Poland's 10.7 and Czechoslovakia's 8.4 per cent per annum is not wide. Moreover, the comparisons in terms of output per employee are more favorable to Czechoslovakia. The

slovakia had an edge over the non-Communist countries in enlarging her fuel base, with basic metal industries developing at about the same rate as in the EEC countries. Czechoslovakia fell behind in the consumer goods industries, bringing into focus the consumer orientation of the Western economy in contrast with the growth orientation of the planned economy. Table 6 presents average annual growth rates for four periods: 1948 to 1959, 1950 to 1955, 1955 to 1959, and 1937 to 1957.²³ Taking the twelve postwar years as a whole, Czechoslovak industrial output grew at about the same rate as that of the non-Com-

²³ The semi-official "provisional index" published by the State Statistical Office has been used for the extension of the new index of output to prewar years; indexes for individual industries have been reweighted by 1948 weights [37, pp. 287-89].

munist countries. The same observation holds for the period 1950 to 1955, and for 1937 to 1957. Considering the preference given by planners to this sector of the economy, it is interesting that Czechoslovak industry did not register a faster rate of growth than its Western counterparts.

The performance of Czechoslovak industry was strong, however, in the second half of the 'fifties. Should the country's growth registered during this period continue in the future,²⁴ Czechoslovakia would catch up with, or forge ahead of, both its Western²⁵ and Communist neighbors.

III. *Concluding Remarks*

Viewed in historical perspective, the industry of today's Czechoslovakia was created to serve the large and assured market of the Austrian monarchy. When an independent Czechoslovak state was created in 1918, it inherited 35 per cent of the monarchy's population, but 75 per cent of her industry (75 per cent of the output of hard coal, 60 per cent of machinery, 75 per cent of chemicals, 92 per cent of glassware, etc.) [4, p. 5]. After a brief interlude between the two World Wars, when the country's industry depended heavily on the world market as a source of raw materials as well as an outlet for finished products, Czechoslovak industry was redeveloped to serve another large market, this time the market of the Communist bloc.

The transformation was accomplished largely by giving top priority to one sector of the economy. During the period under consideration, industry received more than 40 per cent of all investment. The per capita investment in this economic sector was twice the per capita investment in other spheres of material production. As a consequence, industry's fixed capital assets increased by more than 80 per cent between 1948 and 1959, compared to a 50 per cent increase for the whole economy [36, pp. 41, 90, 101, 103] [35, pp. 89, 97, 99]. A similar preference was shown in the allocation of the labor force: while industrial employment increased by 44 per cent, employment in the rest of the economy showed a slight decline.²⁶

The preference of the planners for a specific pattern of industrial growth is revealed by Table 3. The trend described there has con-

²⁴ Taking 1960 = 100, the third five-year plan calls for an increase of gross value of industrial production by 56 per cent by 1965, implying an average annual increase of 9.3 per cent [61, p. 882].

²⁵ The comparison for the last years would be more favorable to the Western countries if the year 1960 were taken as terminal year. Total output of the EEC countries increased by nearly 12 per cent between 1959 and 1960: France, 12 per cent; Germany, 11 per cent; Italy, 15 per cent; Netherlands, 13 per cent [24, p. 2].

²⁶ Agricultural employment decreased from 2,239 thousand in 1948 to 1,623 thousand in 1959 [36, p. 90].

tinued in the third five-year plan currently in operation. Compared to 1960, machinery output is to increase by 83 per cent and chemicals output by 97 per cent, while the consumer durables and the provisions industry are scheduled to increase by 26 and 29 per cent respectively. The third five-year plan continues the stress on industry: investment in this economic sector is to be 88 per cent above the realized investment of the second five-year plan (1955-1960), while average investment in the whole economy is to increase by 59 per cent [61, pp. 882-85, 889].

By gaining political control of Czechoslovakia, the Soviet Union acquired control over a skilled industrial labor force and technical know-how, as well as over large and underutilized industrial capacity. Czechoslovakia has been assigned an important role, first, in the post-war industrialization drive of the Soviet Union;²⁷ second, the industrialization scheme of the East European bloc²⁸ which may compete as an economic power with Western Europe within one generation; and third, the Communist penetration of the markets of the underdeveloped countries.²⁹

APPENDIX: CONSTRUCTION AND EVALUATION OF THE NEW INDEX

The new index of industrial output presented in this paper is based exclusively on Czechoslovak sources such as releases of the State Statistical Office, the State Planning Office, and publications of production ministries, as well as on information contained in various articles.

The classical Laspeyres formula has been used in the computation of the new index. Total output (i.e., output of both industry proper and manufacturing crafts) has been divided into 17 industries with 70 sectors. Six of these sectors have been further subdivided into 36 product groups. The growth of output in crafts is measured by employment; the growth of output for the product groups (or sectors) in industry proper is measured by output of products aggregated by 1948 wholesale prices.³⁰ A product-group index thus takes the form:

$$(1) \quad G = \frac{\sum Q_{ni} P_{oi}}{\sum Q_{oi} P_{oi}}$$

²⁷ For example, exports of machinery and equipment, which represented one-fourth of Czechoslovakia's exports to the Soviet Union in 1949, increased to one-half by 1958 [40, p. 55] [41, p. 4] and the volume of machinery and equipment exports is to increase by 2.6 times between 1958 and 1965 [41, p. 6].

²⁸ In 1958, 45 per cent of Czechoslovakia's machinery exports went to the member countries of the Council for Mutual Economic Assistance. This percentage is scheduled to increase to 60 by 1965 [9, p. 27].

²⁹ Trade turnover with underdeveloped countries reached 11.4 per cent of Czechoslovakia's total in 1958; this represented 38.7 per cent of its trade turnover outside the Communist bloc [11, p. 5].

³⁰ In a few instances 1947 wholesale price ratios, 1948 average export prices, or such indicators of relative scarcity as "plan fulfillment coefficients" were used.

where Q is the quantity in physical units and P is the per unit wholesale price of the i^{th} commodity; the subscript n denotes the current period and the subscript 0 the year 1948.

Product-group (or sector) indexes are aggregated into indexes for individual industries using compensation of employees in lieu of value-added weights:

$$(2) \quad I = \sum G_i \frac{W_i}{\sum W_i}$$

where W_i is the total wages and salaries payments in the i^{th} product group or sector in 1947.³¹

Estimates of value added, derived by subtracting from the value of sales of each industry the value of purchases on current account, have been used at the last stage of aggregation:

$$(3) \quad O = \sum I_i \frac{V_i}{\sum V_i}$$

where O is the index of total output of industry, and V_i is the value added in the i^{th} industry in 1948.

The products used in computing the index are final outputs for the corresponding product-group or industrial sector. Whenever data were missing for some years, the usual assumption was made that the incomplete series move in step with the remaining series representing that particular group. Products for which data became first available after the base year have been linked in. The available sample of products also contains a few commodities, such as aluminum, passenger river boats, motor scooters, or polyvinyl chloride, which were first produced in important quantities after the base year. These new products have been added to the appropriate commodity groups.

The new index of output purports to measure the growth of value added in Czechoslovak industry between 1948 and 1959. Lack of data on inputs of industrial materials in 1948 prices precluded the construction of a net value index; the new index follows the Western statistical practice of index number construction and seeks to approximate a net value index by an index of final outputs combined by value-added (or approximations to value-added) weights. Such an index may differ from the magnitude it is designed to measure for four reasons: first, because of an inadequate weighting system; second, because of an unrepresentative sample of products; third, because the index of final outputs of each product group did not move identically with value added for that group; and fourth, because employment in crafts failed to measure correctly the net output of this economic sector. We shall consider separately each possible source of bias.

1. The ideal system of weights for the new index would be a set of value-

³¹Data on wages and salaries for 1948 are not available in sufficiently detailed breakdown.

added weights for each output. A substitute weighting system introduces a bias in the measured rate of growth if a correlation exists between the growth of the constituent series and their relative over- or underweighting by substitute weights. There appears to be no reason why such a correlation should exist in industrial sectors and product groups within which substitute weights—compensation of employees and wholesale prices—have been used.

In order to estimate the magnitude of bias which could be introduced by the wages and salaries weighting procedure, the following test has been performed on the industry of the Federal Republic of Germany, which is similar to Czechoslovak industry both in structure and pattern of postwar growth. The official German industrial production index has been recalculated by applying wages and salaries in lieu of value-added weights to 31 industries and industrial sectors for which the necessary data were readily available [33, pp. 220-21] [31]. While industrial output of the Federal Republic doubled between 1950 and 1957, the difference between the official and the recalculated indexes remained negligible in all years. Thus it is not likely that the substitute weighting system, used in the calculation of the new index of Czechoslovak industrial output at a lower level of aggregation than in the recalculated index for Germany, introduces a bias in the measured rate of growth.

2. The problem of representativeness of the available sample appears more troublesome. Lack of data does not permit calculation of a coverage ratio for any year, but an evaluation of coverage by inspection is possible. It can be done, for example, by comparing the available sample of products with the extensive list of outputs planned for the year 1953, when industrial planning was already all-inclusive [53, pp. 103-23]. The coverage of civilian production and the distribution of products among various industrial sectors and product groups appear satisfactory. The problem of new products does not loom as large in the case of Czechoslovak industry as in the case of an underdeveloped country. Czechoslovakia was economically advanced in 1948, and genuine new products, as opposed to new models of the same product, did not play a crucial role in its industry's growth. The omission of military items from our sample offers a special problem. Munitions production was probably concentrated in the machinery sector, whose output increased 3.6 times between 1948 and 1959. Since munitions production is included in the weight of the machinery sector, the degree of bias due to omission of military items should not be serious unless the growth of munitions production differed substantially from the rapid growth of civilian machinery production.

A numerical estimate of the possible bias due to the unrepresentativeness of our civilian sample has been derived once more from the industry of the Federal Republic of Germany. The information on Germany's industrial output in physical units has been artificially restricted to the same degree as the information available for the Czechoslovak industry. Applying the 1950 wholesale prices as weights within industries and industrial sectors, and the official value-added weights among industries, a "restricted sample" index has been calculated for the Federal Republic [33, pp. 220-21] [32]. The official and the restricted sample indexes for the whole of industry do not differ in

any year by more than 5 per cent, lending thus some support to the contention that the sample for Czechoslovak industry is representative.

3. The third assumption deals with the relative movements of the value of final outputs as compared to movements in value added. If, for example, purchases from outside constituted an increasing portion of value of final sales of a commodity group, the index would overestimate the growth of value added of that group. However, the period covered by the new index is relatively short and the division of total output into industrial sectors and product groups is quite detailed. Consequently, this consideration does not seem important.

4. Lastly, measuring the output of manufacturing crafts by employment implies that no changes in productivity in the crafts sector occurred during the period under consideration. Generally such an assumption would be of doubtful validity. The assumption seems plausible in the case of Czechoslovakia, considering the fact that as a form of organizing manufacturing activity the crafts sector was doomed right at the beginning of the period. It is not likely that either new investment or improvements in management and organization which would affect productivity occurred in the sector after 1948.

I have defended, so far, the reliability of the new index of Czechoslovak industrial output in an essentially negative way, maintaining that there are no apparent reasons why the measure should suffer by a significant bias in either an upward or downward direction. A more positive approach to the question of reliability of the new index is possible. The new measure is supported by two calculations of growth of Czechoslovak industrial production which are independent of the new index of output. The first one is based on Seton's method of estimating growth of Soviet manufacturing output during the past decade [28]. Searching for a measure which would avoid both the assumption of representativeness of the available product sample and the problem of weights to be assigned to these series, Seton found that a close relationship existed in Western countries between manufacturing output and consumption of fuel, electric power, and steel. The technological conditions representing the relationships between manufacturing output and the three inputs were derived by Seton as coefficients of a multiple regression of manufacturing output on the consumption of these inputs. The coefficients were applied to the Czechoslovak case for the period 1948 to 1953 and for the period 1948 to 1959. The results of the calculation are shown in Table 7.

The second indicator of growth supporting the new index comes from an admittedly unexpected source. As a part of statistics on growth of national income, the Czechoslovak State Statistical Office published for the first time in the *Statistical Yearbook for 1958* the growth of income originating in industry. The official concept of income originating in industry [21], expressed in constant 1954 prices, is much closer to the Western concept of industrial production than to the concept of gross value used in the calculation of the official industrial production index. The growth rate of this measure is also shown in Table 7, together with the official gross value index and the value-added index of output.

It is the author's belief that despite its obvious limitations due to incom-

TABLE 7. MEASURES OF INDUSTRIAL PRODUCTION: 1948-1953 AND 1948-1959

Average Annual Percentage Rate of Increase		
	1948-1953	1948-1959
Official Indexes:		
Gross Value of Production	14.1	11.6
Income Originating in Industry	8.3	8.2
Seton-type Index	7.6	7.9
Value-Added Index of Output	7.7	8.4

Sources: Official indexes: [36, pp. 37, 137].

Seton-type index: [28, pp. 135-136]. The regression equation is: $z = -1.554 + 0.291 f + 0.305 s + 0.582 e$, where z is the average annual growth of output, and f , s , and e are respectively the average annual growth of consumption of fuel, steel and electric power.

Value-added index: Table 1.

plete data, the new index is a reasonably adequate measure of growth of Czechoslovak industrial output between 1948 and 1959.

SIMULATION OF AN ECONOMY WITH DEVELOPMENT AND TRADE PROBLEMS

By EDWARD P. HOLLAND*

Economists cannot make laboratory experiments on national economic systems. If, however, we could devise and build a miniature national economy, complete in every detail, which behaved exactly like a real one but on a much-speeded-up time scale, and if we could adjust its parameters and then manipulate policies and exogenous events while recording time histories of its economic variables—then we could learn much by experimenting with it. By means of simulation with a computing machine, we can do something of that kind. Although we are forced by practical considerations to simplify the representation of the economy, using aggregate variables and omitting many details, we can, nevertheless, simulate and explore an economic-system model which behaves much more realistically than any model that can be dealt with by conventional analytic techniques.¹

The purpose of this article is to illustrate how the technique of simulation can be used to study problems of economic development and foreign trade policy for an underdeveloped country. Graphical and numerical results from a few computer runs are presented and compared to show how simulation might actually be used as an aid in formulating a development investment program.

These runs are a small sample selected from about 200 made during

*The author, while directing the project on which this article is based, was a research associate in the Center for International Studies at the Massachusetts Institute of Technology. He was assisted in the work by Benjamin Tencer and Robert W. Gillespie. The author is now associated with the Simulmatics Corporation of New York.

This work was financed jointly by the Center for International Studies and two other M.I.T. units: the Research Laboratory of Electronics and the Sloan Research Fund of the School of Industrial Management. An earlier analog simulation project, out of which this project developed, was financed by a grant from the Rockefeller Foundation. Assistance in making the transition to the digital computer, using the DYNAMO program, was rendered by the Industrial Dynamics Group of the School of Industrial Management. Services of an IBM 704 computer were provided by the M.I.T. Computation Center.

¹An over-all picture of the state of the art of simulation, with some of its history, rationale, methods, and typical applications, is given in a symposium of articles in the December 1960, *American Economic Review* by Orcutt [6], Shubik [9], and Clarkson and Simon [2]. Bibliographies with these articles cover a wide variety of simulations and background material, unfortunately omitting, however, the interesting analog work of A. W. Phillips [7] [8].

experiments on the model to be described. The parameters and initial values of variables in the model were based largely on the Indian economy as of 1951. The development programs and policies which were tried out on the model, however, were purely hypothetical and do not have any relation to actual experience or plans of the Indian government. No policy recommendations for India should be inferred from the results presented, because, for simplification, several considerations have been omitted which might be crucial for India. The work done was partly a process of developing a technique and partly a study of some hypothetical situations. Use of this method for policy guidance in real situations is a phase that is yet to come.

The objectives of a simulation study may include establishing a consistent and technically feasible development plan, exploring the effects of changes and alternatives in such a plan, and discovering what variables provide the best signals to tell how well the plan is succeeding or to warn of impending trouble. Other objectives include designing policy measures for handling problems that may originate either inside or outside the system, discovering what side effects are likely to be induced by any given policy, and finding out how to cope with such effects if they appear. For these purposes, simulation offers several advantages. It makes it possible to observe the dynamic interaction of aspects of the economy which are usually analyzed in isolation from each other, such as foreign trade, consumers' behavior, and investment decisions. It also permits comparatively realistic representation of all sorts of nonlinearities, discontinuities, time delays, and irreversibilities. Inclusion of such characteristics at the appropriate points is usually crucial for reproducing the modes of dynamic behavior that can occur in the real system.

I. The Economic System Model

In the description that follows the aim is to give a picture of the main features of the system; including fundamental assumptions about what elements of the structure are constant, which variables are exogenous and which are endogenous, and what sort of relationships control each of the main variables, with due attention to nonlinearities and other special characteristics. It would not be practical, in a short article, to describe such a complex model, or even a part of it, in equations, because it would require so many of them, with so much explanation, to be meaningful.²

An actual developing economy would be observed and analyzed in

² A complete specification, for those who want it, is included in [5]. Not counting about two and one-half chapters of introduction, it occupies 167 pages and takes more than 250 equations.

terms of the time histories of such variables as gross national product at current prices, real gross national product, consumers' price index, price indexes for various categories of goods, investment in various sectors, total investment, production from various sectors, imports of various types, exports, and the balance of payments.

The model described here was formulated with the aim of making the counterparts of these variables behave realistically under dynamic conditions. This meant representing underlying processes of adjustment pertinent to nonequilibrium situations rather than merely relationships which must exist between variables when they are in equilibrium.

Thus, for example, long-run supply curves were not used, because the relation between price and supply quantity at any future time will be affected by the particular paths along which some of the other variables move during the process of change and because the occurrence of a long-run type equilibrium is extremely improbable under the conditions for which the model was designed to be used.

Instead, very-short-run supply functions for the various sectors of the economy were formulated, with parameters subject to continuous change, reflecting changes in available fixed capital, prices of intermediate goods, wage rates, and labor productivity. A short-run supply curve for the product of one of the industrial sectors would look at a particular time like curve *a* of Figure 1. The part of the curve to the left of the kink is based on variable costs, with the assumption that only enough plants operate to produce the total output efficiently. To the right of the kink all plants are assumed to be operating at or above their normal output, and the price of their product is affected by scarcity. If net capital formation were carried out with no change in wage rates or intermediate-goods prices, the supply curve at some later time would have shifted horizontally to a position like *b*. (The lowering of the intercept on the price axis reflects increased productivity in new, technically improved plants.) If the same capital formation had been accompanied by a 50 per cent increase in wages and other prices, the short-run supply curve would have shifted to *c* instead of *b*.

The model includes six domestic production sectors, of which four have short-run supply curves similar to that described above. The four are power-using consumer goods manufacturing (Sector 1), capital and intermediate goods production (Sector 3), nonpower-using consumer goods manufacturing (Sector 4), and transport, communication, housing, etc. (Sector 5). In addition, the supply of output from agriculture (Sector 2) is assumed to be completely inelastic in the short run, and the supply of personal services (Sector P) is assumed

FIGURE 1. SHORT-RUN SUPPLY CURVES

to be perfectly elastic on any time scale. The model also has three sectors concerned with imports and exports (Sectors 6, 7, and 8).

Associated with each of the first five production sectors named above is a capacity-creating activity which can maintain or expand the sector's capacity or allow it to decay. At any given time decisions are being made about undertaking capital formation projects in each sector, both for replacement and for expansion. (The determination of these decisions is explained in Section II.) The units of productive capacity started during a particular time increment (the increments used were .05 year long), continue under construction throughout a gestation period and then become available to use for production. Factor payments and capital goods purchases, constituting investment expenditures, are determined at any time by the number of capacity units which are in the gestation process. The units of capacity completed and ready for production in a given time increment remain part of the sector's capacity throughout statistically distributed life spans. Thus, at any time, the rate at which old capacity is decaying, the rate at which new capacity is coming into being, the existing capacity, and the level of investment expenditure all depend on the past history of the rate of starting capacity-creating projects, and whenever this rate of starts is altered, the effects on investment and especially on capacity are delayed and smoothed out.

Demand for the product of any sector may be a combination of consumer's demand, demand derived from the current production of other sectors, and demand derived from capacity-creating projects. Not all of these are relevant to all sectors, however. The significant demand relationships are indicated diagrammatically in Figure 2.

Each block in Figure 2 represents a combination of several rela-

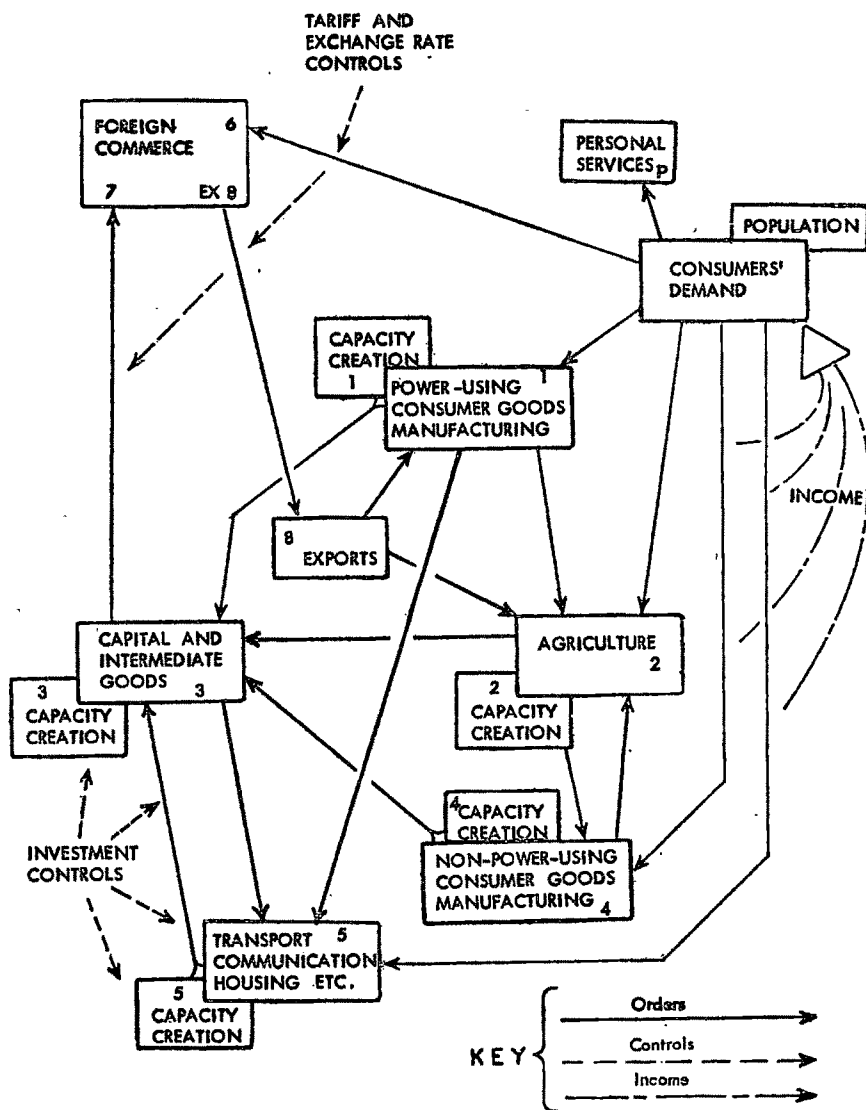

FIGURE 2. NATIONAL ECONOMIC SYSTEM DIAGRAM

tions, and each arrow represents an important signal from one group of relations to another (i.e., a dependent variable from one group entering another group as an independent variable). The block labeled "power-using consumer goods manufacturing," for example, stands for a price-determining function like the short-run supply curve of Figure 1, a function for evaluating the potential return on investment on the basis of current conditions, a wage-negotiation function, which responds to profits and in turn affects costs and the supply price, and a set of input-output coefficients (fixed in real terms) determining the demand by this sector for intermediate goods from other sectors. All of the relations implied in this block are related to current production in the particular sector (Sector 1).

Touching the block described above to indicate a high degree of interdependence is another block representing the capacity-creating activity and the capital life cycle for this sector. Arrows from the current-production block (Sector 1) to Sectors 2 and 5 indicate the demand for products of those two sectors induced by production in Sector 1. Another arrow, going to Sector 3, originates in both the production and capacity-creation blocks of Sector 1, indicating that products from Sector 3 are demanded in proportion to the level of capital-formation activity as well as in a different proportion to current output. For each demand arrow shown it would be appropriate to have a price arrow going the other way, since the prices of intermediate goods used in any sector affect that sector's production cost and hence its supply price schedule. Price arrows, however, have been omitted for clarity.

The export sector, Sector 8, has no production or capital formation and is merely an accounting relationship, combining products of Sectors 1 and 2 into a product-mix for export. The foreign commerce sector includes a fixed supply price (in foreign currency) for imported capital and intermediate goods, another price for consumers' imports, and a demand equation for exports. The price elasticity of export demand may be specified as desired for each run. Exchange rates and tariffs may be held fixed, made flexible, or manipulated in various ways.

The aggregate national income, earned by factors in production and capital-formation activities, is adjusted for taxes and business savings to determine disposable income, which, with a lag, becomes a principal independent variable of the consumers' demand function. The other independent variables are the prices of various goods, determined from the supply functions, and the population. Population grows exponentially at whatever rate is programmed, independently of other variables.

The consumers' demand function has characteristics of a classic multidimensional indifference map, determining the allocation of expenditures in response to income and prices. The per capita demand for food increases less than proportionately as per capita real income rises, in keeping with Engel's Law, while savings and the demands for other goods and for services increase more than proportionately. Various goods (including imported ones) are substitutable for each other at diminishing marginal rates. This demand function and the supply functions for the various consumer goods interact continuously to adjust prices as conditions change.

II. *Specifications for a Run*

Before going on to show how the economic-system model performed in a particular run, it is necessary to indicate what functions and constraints were included as aspects of policy, what variables were assigned exogenous values or time-paths, and what degrees of freedom were kept open.

A development plan was specified in terms of two sets of time-schedules. For Sectors 2, 4, and 5—agriculture, nonpowered consumer-goods production, and public overhead services (transport, communication, housing, etc.)—specific time-programs for starting capacity-creation projects were set up and rigidly followed. This does not imply that the enterprises in these sectors are necessarily government-operated, although some may be. The assumption is that it is government policy that determines the level of capital formation, but the actual investment may be carried out by private entrepreneurs. It has been observed in India, for example, that very little investment takes place in agriculture in regions where no government activity is carried out. Community development programs are an effort by the government to help and encourage villagers to undertake improvements in their facilities and in their methods. Irrigation dams and canals built by the government must, to be useful, be supplemented by local ditches and banks built by individuals or local groups. Thus the privately implemented activity tends to be determined by that of the government.

Development of the small-scale and cottage industries lumped together in Sector 4 is, in India, also induced largely by government incentive, even though the actual firms are privately owned. In Sector 5 there is a combination of private enterprises encouraged and regulated by government—such as part of housing—with purely government-owned utilities like power and railroads. For the purposes of this study we are not concerned with ownership, nor with the question of how control is effected, but only with the fact that in these three

sectors it is reasonable to assume that government policies control the rate of capital formation.

For Sectors 1 and 3—the modern industrial sectors producing respectively consumers' goods and intermediate and capital goods—time-programs were specified for the *minimum* rates of starting capacity-creation projects. These sectors have private investment decision functions based on profits, and it is expected that these endogenous mechanisms will often sustain higher rates of project starts than the minimums. However, in the event that starts in either of these sectors should fall below the levels specified, it is assumed that some action will be taken to stimulate them—perhaps direct government investment, perhaps financial incentives to private investment; again we do not identify the means of carrying out the policy but assume that some action can be devised that will prevent capital formation in each of these sectors from falling below the specified minimum at any time.

The private investment decision function in each of these two sectors is primarily a response to the profit rate, determined from the current market price and production costs in a new plant. This profit margin is reduced to a rate of return on the basis of the cost of building new capital facilities. Adjustments are made for overhead and financing costs and in some cases for optimism or pessimism of entrepreneurs. Near-future replacement requirements are taken into account, as well as the amount of new capacity already under construction but not finished. The outcome of all these considerations at any time is the rate at which private entrepreneurs want to start new projects in each sector. This will be the actual rate if it is above the scheduled minimum and below any ceiling that may be imposed.

Ceilings on the rate of starting capital projects were called for, under certain conditions in some runs, as measures to combat inflation or to reduce imports of capital goods. The means of effecting this control are not included in the simulation. They might be restriction of import licenses, direct limitation of construction, or indirect limitation through a tight money policy.

Besides the capital-formation profiles—definite ones for Sectors 2, 4, and 5, and minimum levels for Sectors 1 and 3—specifications of foreign-trade policy were included. The exchange rate was fixed, with no provision for changing it in this run. A tariff mechanism was set up to protect the capital-and-intermediate goods sector by raising the tariff on equivalent imported goods if any domestic capacity became idle. A tariff on consumers' imports was specified to be imposed in case of a crisis in the balance of payments (defined, for this run, as a current-account deficit greater than \$500 million per year). The tariffs were increased periodically if the situation for which they were

invoked persisted. A definite schedule was assumed for tapering off food imports during the first ten years as home production expanded.

Other assumptions were made, not as policies, but to tie down exogenous variables. The prices (in foreign currency) of imported goods of each type were set at fixed values, independent of quantity and without time variations. The demand for export goods was also devoid of time-trend or cycles but was made sensitive to price, with a value of -1.3 for the elasticity. Population was assumed to grow exponentially with a growth coefficient of .02 per year.

No limit was set either on credit financing of investment (government and private) or on the deficit on current account in the balance of foreign payments. This does not imply that projections of these deficits would not be major considerations in planning or that their actual magnitudes would be ignored in practice. The deficits are determined, however, by the operation of mechanisms which have already been fully specified. As a technique of investigation, they are left open-ended; the resulting inflation and the foreign-exchange deficit are among the criteria that will be used later in this article for comparing different runs.

III. *A Sample History*³

An economic history of the hypothetical country for a 20-year period is shown in Figures 3 and 4. This is part of the output generated in one computer run, referred to here as *Run A*. In addition to plotting the points through which these graphs were drawn, the computer tabulated values of about 80 variables by half-year intervals. (The computations were made at intervals of $\frac{1}{20}$ th of a year, approximating a continuous process, and involved many additional variables, but since it would not be worth while to record every step of the computations, selected values were actually tabulated only by half-year intervals.)

For this particular run a relatively intense program of investment in public overhead (Sector 5) was carried out, with considerable emphasis also on the capital and intermediate goods industries (Sector 3). Agriculture (Sector 2) was expanded enough to replace food imports and increase the food supply about 4 per cent per year, twice as fast as the population was growing. Relatively little emphasis was given to consumer goods manufacturing (Sectors 1 and 4). This program is of a type often advocated for starting a development process; similar programs are being followed in a number of developing coun-

³ Most of the time-history graphs that are presented in this and the next section are from Tencer [10].

tries. It is based on the theory that the low levels of public overhead capital and of capital-goods capacity are bottlenecks and that investment in those sectors will induce expansion of consumer goods manufacturing both by opening the bottlenecks and generating demand.

The real investment carried out in each sector is shown in the bottom part of Figure 3. In Sectors 2, 4, and 5, as explained above, these real investments were rigidly programed. In Sector 3, the profit-motivated level of investment rarely came up to the programed minimum; thus the latter almost always became the actual value. In Sector 1, on the other hand, the private investment induced by profit expectations was almost always above the low minimum set by the program.

With this investment program as prime mover, and with unlimited credit and foreign exchange, the gross national product in current prices increased dramatically—at an average rate of 7.5 per cent per year (see the middle part of Figure 3). A large part of this increase, however, was not growth of real output but only a rising price level. Even so, real gross national product, as shown, became more than $2\frac{1}{2}$ times as great in 20 years, an average growth rate of 4.8 per cent per year. Growth of real disposable income per capita averaged 2.8 per cent per year.

Gross investment is shown as a percentage of gross national product at the top of Figure 3. This percentage was a dependent variable, inasmuch as GNP was generated within the system while real investment was independently programed. Starting from about 10 per cent of national product at the beginning of the run, gross investment increased to 20 per cent in the middle of the run and then declined very slightly. Figure 3 also shows the annual rate of increase of the consumers' price index, which was in the neighborhood of 3 per cent per year throughout most of the run, and the balance-of-payments deficit on current account, to be discussed below.

Figure 4 shows the behavior of prices and wages, the changing pattern of consumption, and, at the bottom, the various components of foreign trade and the resulting balance on current account. Except in Sector 5, where capacity was very rapidly expanding, prices rose generally. Industrial wages rose even faster, partly because of increasing labor productivity in the industrial sectors. The price of consumers' imports, P6, was rapidly elevated by an almost continuous succession of tariff increases, intended to help improve the balance of payments.

The growth of consumption of different kinds of goods and services followed Engel's Law, in that expenditures on food, initially high,

FIGURE 3. A SAMPLE HISTORY: PART OF RESULTS FROM RUN A

FIGURE 4. ADDITIONAL RESULTS FROM RUN A

grew less rapidly than other expenditures as per capita income grew. (This refers to basic foodstuffs; extra processing of food is in a different sector.) In addition to consumption measured in current values, the graph includes physical quantity indexes for industrial manufactures (Q1), small-scale and handicraft products (Q4), and consumers' nonfood imports (Q6). The choice among these three goods was relatively sensitive to price changes. Thus, as P1 climbed more steeply than P4, the consumption of Q4 caught up to that of Q1 (in terms of quantity). It is evident also that the ever-increasing tariff included in P6 was effective in holding down the quantity of Q6 consumed.

Although consumers' expenditures on nonfood imports, C6, doubled in 15 years and reached $3\frac{1}{2}$ times the initial value in 20 years, the increase went into tariff revenue and not into payments abroad. In the bottom panel of Figure 4, where the balance-of-payments components are shown, it can be seen that the expenditure abroad for consumers' nonfood imports was actually reduced during the first 15 years, and in spite of some increase thereafter was still below the initial value by the twentieth year.

Imports of food were gradually tapered off during the first $9\frac{1}{2}$ years as part of the program—not in response to market forces. Imports of capital goods rose rapidly during the first 12 years as required for the high rate of capital formation but declined thereafter as the domestic capital goods sector reached a sufficiently rapid rate of growth to begin taking over the supply. Imported intermediate goods, on the other hand, were assumed to be of types for which domestic substitutes were not developed within the 20-year period. Thus expansion of the economy induced ever-increasing imports in this category. With exports declining because of the rising price of exportable goods, and with imports of intermediate goods steadily rising, the import-replacement process in the food and capital goods sectors was not sufficient to bring the balance-of-payments deficit below the billion dollar a year level.

The initial assumption that this balance-of-payments deficit could be financed by long-term capital inflows is clearly open to question, not only because of the magnitude of the accumulated deficit over the 20-year span but also because even at the end of the 20 years the deficit continues at a rate of more than \$1 billion per year. The rate of inflation, too, while not catastrophic, might be considered undesirably high in itself (in addition to its adverse effect on foreign trade). Thus, although the investment program and other policies used in Run A produced a significant rate of economic growth, the results cannot be accepted as satisfactory. Let us then see whether the program can be modified to keep the price level from rising so fast

and to reduce the amount of foreign exchange used up by the deficit in the balance of payments.

IV. Effects of Some Changes in Plans and Policies

The simulation was repeated a number of times with a series of cut-and-try changes to help in understanding the dynamics of the system and to seek an improved plan for the allocation and phasing of investment and improved policies for control of foreign trade. The last of the further runs described here is by no means an optimal solution, nor is it in fact an adequate solution for the long run, inasmuch as another crisis is imminent at the end of the period considered. Nevertheless, these runs show some improvement and illustrate the process of investigation. What is lacking is simply further application of the same approach to arrive at a still more satisfactory policy combination.

Run B: Considering that the price inflation and heavy imports of capital goods in Run A are both associated with a high level of investment, it is appropriate to try cutting back the investment program to see what improvement might be made in price stability and the balance of payments and at what cost in growth of real output. Accordingly, Run B was made with about 20 per cent less investment in Sector 2 (agriculture), Sector 3 (capital and intermediate goods), and Sector 5 (public overhead). The main results from this trial are shown in Figure 5, together with the corresponding results from Run A and from other runs yet to be discussed. The less intense program, as expected, reduced the balance-of-payments deficit significantly by reducing capital goods imports. It is noteworthy, however, that the reduction in investment did not reduce the rate of inflation at all. In fact, the final value of the consumers' price index was actually a shade higher for Run B than for Run A (1.65 against 1.62). Evidently the slower growth of consumers' demand was offset by the reduced rate of expansion of supplies.

The reduction in investment, while ineffective in abating inflation, caused a significant loss in growth of output. Starting from 106 billion rupees per year initially, real gross national product grew in 20 years to 237 billion rupees per year in Run B, as compared with 270 billion rupees in Run A. This is an average annual growth rate of 4.11 compared with 4.78 per cent per year.

These comparisons, and others to come, are summarized in the table at the bottom of Figure 5.

Run C: An attempt was made to alleviate inflation by applying the following policy, leaving everything else as it was in Run B: Whenever the rate of change of the consumers' price index reached 3 per

FIGURE 5. EFFECTS OF INVESTMENT PATTERN AND POLICY CHANGES

cent per year, the rate of starting new capital projects in the industrial sectors (1, 3, and 5) was curtailed until such time as inflation of the price index fell below 3 per cent per year, whereupon the program of Run B was resumed.

This policy was first invoked in Run C about $8\frac{1}{2}$ years after the start, when the inflation rate first reached 3 per cent per year. The resulting drop in investment is noticeable in the graph at the top of Figure 5, while in the one just below, it can be seen that the policy did indeed have the effect of reducing the rate of inflation to less than the chosen limit. This was not a major reduction, however, since it had not been very much above 3 per cent for much of the time in Run B. A slight drop in currently priced national product is noticeable, but real product was almost identical in the two runs. The most notable effect of this "anti-inflation" policy proved to be a reduction in the balance-of-payments deficit, through reduced imports of capital goods.

*Run E:*⁴ The fact that reducing industrial investment during part of Run C saved foreign exchange and slightly reduced inflation without significantly hurting real growth suggested that the investment pattern was too heavily biased toward the industrial sectors and that some gain might be effected by shifting emphasis away from some of them. Therefore Run E was programed with 10 per cent less investment in public overhead capital than Run C but with a 25 per cent increase in agricultural investment. The graphs and table tell the story: significantly less inflation, higher real output, and another \$800 million saving in foreign currency.

Run G: Between Run E and Run G a good many exploratory runs were actually made, and the program was changed in several respects. The investment pattern was changed further in the direction of less public overhead (Sector 5) and more agricultural expansion (Sector 2). The capital and intermediate goods program (Sector 3) was smoothed out a bit and built up a little earlier, while investment in nonfood consumer goods manufactures (Sector 1) was accelerated after the tenth year. Only in nonpowered consumer goods production was the program left unchanged. The new investment profiles (as they actually occurred, including some spontaneous investment) are compared with those of Runs A and E in Figure 6. The changes in the Sector 3 program, which were intended to smooth out the actual investment profile in that sector, did not have that effect, but instead simply changed the timing of the fluctuations in spontaneous investment.

As a measure to inhibit inflation, especially when a sudden policy change might set up a sharp transient stimulus (e.g., in case the

⁴ Runs D and F have been omitted from the sequence.

currency should be devalued), the time lag in the wage increase function was doubled, implying some sort of wage control policy. This change does not alter the equilibrium or target level toward which wages move under any given set of conditions but slows down their adjustment toward that target.

For the first 10 years this program gave a much better result than the previous ones (see Figure 5). Real gross national product grew faster, with less inflation, and with a diminishing balance-of-payments deficit. With the main emphasis on sectors requiring less capital goods, capital goods imports were eliminated after 9½ years, at the same time that food imports were phased out and just after the balance-of-payments deficit had been brought to zero.

At that point the character of the process changed abruptly. The abruptness resulted from the crudeness of approximations used in the

FIGURE 6. TIME PROFILES OF REAL INVESTMENT, RUNS A, E, AND G

model formulation, but the nature of the change is indicative of a problem that is actually of concern in some developing countries. That problem is the difficulty of indefinitely continuing the import substitution process. As more and more imports are replaced, the remaining opportunities become less and less attractive or feasible. In this model, the effect of this decreasing flexibility was roughly approximated in the nonfood consumer goods category by the diminishing marginal rate of substitution in the demand function. For either food or capital goods, however, import substitution remained perfectly feasible until all such imports, and therewith, of course, the substitution possibilities, were suddenly eliminated. The resulting shock was enhanced in this run by the accidental simultaneity of this event in the case of both food and capital goods imports.

Before the elimination of these imports $9\frac{1}{2}$ years from the start of the run, a favorable trend in the balance of payments had been established by the reduction of these imports faster than imports of consumer goods and intermediate goods were increasing. (Exports were hardly changing.) Afterward, the continuing increase in consumers' and intermediate imports rapidly built up a new balance-of-payments deficit.⁵ The ending of the import-substitution process affected consumers' prices favorably, largely because the rate of expansion of agriculture was maintained, with all of the increase being added to the supply instead of some being offset by reduced imports. Not only was inflation checked but from the twelfth year on the consumers' price index even declined.

By the time the current-account balance-of-payments deficit had grown from zero to \$600 million per year in four years, and was still increasing at about the same rate, it seemed time for some drastic countermeasures. Several experiments were tried, only one of which is reported here. When the deficit reached \$600 million per year ($13\frac{3}{4}$ years from the start), the currency was devalued so that 50 per cent more rupees were required in exchange for a dollar, and at the same time a 20 per cent tariff was imposed on consumers' imports.

The short-run impact was an improvement in the current account of \$750 million per year, as seen in Figure 5. Of the total, \$600 million was from reduced consumer-goods imports and \$150 million from

⁵ Of course, it is just as unrealistic to assume no substitution possibilities for intermediate goods as to assume the possibilities are perfect for capital goods. Undoubtedly these features can be improved in a future model. However, except for the sharpness of the discontinuity, these approximations compensate each other to some degree. It is not the object of this article to draw general conclusions but to illustrate a technique of investigation.

increased exports. This improvement may be regarded as permanent, relative to the deficit that would otherwise have developed if it could have been financed and allowed to grow indefinitely. A more realistic interpretation, however, is that a crisis was impending and was deferred for a few years by the devaluation. Although the balance of trade deficit was greatly reduced, its rate of growth was not affected, as can be seen by comparing the slopes of the balance-of-payments graph of Figure 5 for the periods before and after the devaluation (before year $13\frac{1}{2}$ and after year $14\frac{1}{2}$). By the twentieth year the deficit had reached \$700 million per year and showed no sign of leveling off.

This illustrates the need for some action outside the range of the assumptions used thus far in the investigation. With the fixed export demand scheduled assumed in these runs, and the requirement of intermediate-goods imports in proportion to the growing output of a domestic industrial sector, there is really no way to stabilize the trade balance, even if all consumer and capital goods imports are cut off. Although the limitations assumed are reasonably realistic for some countries at some stage in their development, they cannot be tolerated in the long run and must somehow be overcome.

With the assumed limitations, as long as growth is successfully maintained, measures acting through price effects (i.e., tariffs and devaluation) give only temporary relief. To effect a more permanent improvement it would be necessary either to develop domestic substitutes for all imports and work toward autarky or to expand export demand through successful promotional campaigns abroad and the development of production of new export goods. Attempts to solve the balance-of-payments problem without such measures may be observed in some real countries; perhaps this simulation helps to show why they seldom succeed.

Although it ended with a problem still to be solved, Run G was on several counts an improvement over the previous ones. The growth of output was a little faster than in Run A, and significantly faster than in the intervening runs, while the over-all rise in the price index was the least, and the total drain on foreign exchange reserves was only a fraction of that in the other runs. (See the table in Figure 5.) On the other hand, the slower accumulation of industrial productive facilities left the economy at the end of the run less well equipped for future expansion.

The great improvement made by reducing investment in public overhead capital could mean either of two things: It could mean that the original program was actually too heavily slanted toward public overhead capital. More plausible, however, is the possibility that the

assumptions about requirements for overhead services were not realistic. A large part of the output of this sector, according to our statistical sources, was used by consumers. The assumption that their demand for these services (including housing) was neutrally price-elastic should surely be questioned. Also, it might be desirable to subdivide the sector into services primarily for industries and those primarily for consumers.

V. Concluding Observations

From the series of examples presented here it is apparent that an evaluation of policy alternatives for an actual situation could well involve scores or even hundreds of runs, depending on the problem addressed, the freedom available for variations in different dimensions of policy, and the degree of certainty with which the economic system structure is known. Obviously no substantive conclusions could be drawn from these few runs. In fact, critical consideration of the results led to questions about the validity of assumptions underlying the balance-of-payments problem and the requirements for public overhead services, and to suggestions for trying to improve the formulation.

There is, of course, nothing unique about simulation that makes its results more dependent on assumptions than any other method. The assumptions in such a model as this are so explicit and so numerous as to emphasize the dependence. It is less noticeable in more simplified analyses where it is implicitly assumed that all sorts of things can simply be omitted from the model, but it is no less limiting. A simulation study easily can, and always should, include tests of the effects of changing questionable assumptions or parameter values, at the same time developing ways to make the success of policies relatively insensitive to such changes.

It is not to be expected that simulation, using an approximate model whose parameters are not precisely known, will produce an accurate forecast for a 10-, 20-, or 30-year period. Apart from shortcomings of the model, events exogenous to the real system may easily start cumulative processes leading to major deviations from what was otherwise the most probable outcome, so that no technique can yield reliable predictions. The purposes of a simulation study are to learn about possible problems and how to cope with them, and to make long-range projections for a variety of contingencies, in order to provide perspective for working out shorter range policies. Like an itinerary for a long trip, a long-run plan should be subject to revision whenever new knowledge or new opportunities warrant, or whenever unexpected obstacles arise. At any time it is desirable to have some

vision of long-run goals, as well as more detailed targets for the shorter run together with plans for attaining them. Thus a 20-year projection provides a frame of reference within which to work out a 5-year plan, so that the 5-year planners will not, for example, under-rate worth-while projects that take 6 years to become productive.

Either for working out development plans or for devising measures to deal with particular dynamic problems, simulation offers some powerful advantages over other techniques. One is the capability of handling a relatively complete system—one which provides for dynamic interactions between aspects of the economy that are usually analyzed in isolation from each other. The value of this is illustrated by some not entirely obvious conclusions from a study of exchange-rate devaluation which was made by Robert W. Gillespie [3] using this same model. He found that for this model and the assumed conditions the most important determinants of the effectiveness of devaluation were not the frequently analyzed elasticities of demand but the induced effects on the pattern of investment allocation and the resistance of the system to inflation of prices. The resistance to inflation, in turn, proved upon further testing to be very sensitive to the speed with which consumers adjust their expenditures to changes of income.

These results cannot, of course, be taken as general, being based on a partial survey of a particular model. However, they do make it clear that some of the most innocent-appearing *ceteris paribus* assumptions can be treacherous, and that exchange-rate policy had better not be decided purely on the basis of comparative statics. Far-sighted theoreticians and policy-makers have already described the processes involved here and how they pertain to the effectiveness of a devaluation [1] [4]. But until the development of simulation, the means of exploring the problem fully have been lacking, and little has been done about it on the theoretical level beyond discussion.

As compared with maximization techniques, simulation permits a clearer separation of the technical investigation from the defining of policy objectives. No formal welfare function or over-all performance index is needed in the analysis itself. Thus it is not necessary to formulate value judgments in a vacuum before observing the effects of alternative policies. Since the effects show up as changes in such incommensurable criteria as the time profiles of income, employment, and prices and the stability of the foreign exchange rate, any such formulation is extremely dubious. A better approach is to choose among alternative outcomes in terms of all of their dimensions. With simulation this can be the final step and can be done, if desired, by decision-makers other than the experimenter.

The formulation of the model for a simulation study is crucial and requires extensive research and good judgment. The techniques of computer programming have developed to such a point that almost anyone can set up some kind of a model and—after some initial difficulties—get it to work. The results, however, may be thoroughly misleading if the model does not correspond suitably to what it is supposed to represent. The importance of careful formulation of the model applies both to its qualitative structure and to the numerical magnitudes involved. Actually a good deal of insight can be gained—as has often been done with engineering systems—by experimenting with a model with the right qualitative features, such as nonlinearities and time lags, even without much knowledge of the numerical values of the parameters. At least, from such a hypothetical study one can learn what modes of dynamic behavior are possible and which parameters are critical in determining which mode will prevail.

In problems of dynamics it is probably more important to have these qualitative features represented in the right places than it is to have accurate numerical estimates of the parameters. It is not even clear what is meant by the idea of highly accurate estimates of the parameters of a model which is qualitatively wrong. On the other hand, many issues hinge on the quantitative values of parameters. Without some reasonably reliable statistical estimates we are likely to find that certain policy choices simply cannot be made one way or the other. Without some knowledge of the orders of magnitude of the quantities we are dealing with, it is not even possible to formulate a good model qualitatively, for any model must be a simplification, omitting many aspects of reality, and we need some basis for judging what can safely be omitted. It is not great precision but reliable approximations that are needed.

Simulation thus is no substitute for empirical research. In fact it sharpens the need both for statistical information and for accurate descriptions of relationships and dynamic processes. With models carefully formulated from such foundations, the possibilities for increasing our understanding of economic dynamics in general and for developing workable policies for particular situations are great.

NEW CONCEPTS CONCERNING FUTURES MARKETS AND PRICES

By HOLBROOK WORKING*

Research on futures markets during the last 40 years has produced results that have required drastic revision or replacement of a great part of the previously accepted theory of futures markets and of the behavior, not only of futures prices, but of the general class of prices that may be called "anticipatory." New light has been thrown on the behavior of businessmen, including speculators, and on the functioning of the price system.

To say that new theory has been required poorly expresses the consequences of the research, because the main results have not been "theory" in the usual economic sense of that term. One may better follow an example set by Conant when he faced a similar problem in undertaking to explain the nature of science, and said, "... science emerges from the other progressive activities of man to the extent that new concepts arise from experiments and observations, and the new concepts in turn lead to further experiments and observations" [4, p. 24]. The chief result of the research to be considered here has been the emergence of a series of new concepts arising from observation and statistical analysis. They are listed in Table 1, with a parallel statement of the concepts that they partially or wholly displace, and their emergence is traced in succeeding sections of the paper, where the main evidence on which the new concepts rest is summarized.

Empirical research has played a leading role in the advancement of economic knowledge and understanding that is described here, but the role has been a different one than economists have ordinarily thought that such research would play in advancing their science—if economics be a science.¹ In the final section below we re-examine some prevalent views on the function of empirical research in economics,

*The author is associate director emeritus of the Food Research Institute, Stanford University. This paper is a revision of one given, under the same title, at the annual meeting of the American Economic Association, December 22-30, 1960, an abstract of which appeared in *Am. Econ. Rev., Papers and Proceedings*, May 1961, pp. 160-63. The author is grateful for a grant from the Rockefeller Foundation that has assisted preparation of this revision.

¹Most natural scientists, including Conant [4, pp. 26-27], have felt during at least the past half century that economics did not fully qualify as a science. Conant [4, pp. 118-19] reserved judgment on the possibilities of economics becoming a science.

TABLE 1—CONCEPTS CONCERNING FUTURES MARKETS

New Concepts*	Displaced Concepts
1. <i>Open-Contract Concept:</i> Futures markets serve primarily to facilitate contract holding (1922).	Futures markets serve primarily to facilitate buying and selling. (Disproved.)
2. <i>Hedging-Market Concept:</i> Futures markets depend for their existence primarily on hedging (1935; 1946) ^a .	Futures markets depend for their existence primarily on speculation. (Disproved.)
3. <i>Multipurpose Concept of Hedging:</i> Hedging is done for a variety of different purposes and must be defined as the use of futures contracts as a temporary substitute for a merchandising contract, without specifying the purpose (1953).	Hedging is done solely to avoid or reduce risk. (Disproved.)
4. <i>Price-of-Storage Concept:</i> Storage of a commodity is a service supplied often at a price that is reflected in intertemporal price spreads, and because the holding of commodity stocks can afford also a "convenience yield," the price for storing small stocks is often negative (1933; 1949).	Storage of a commodity is a service that is supplied only in response to an assured or expected financial return equal to or greater than the cost, the latter calculable ordinarily without regard to the quantity of stocks to be stored. (Disproved.)
5. <i>Concept of Reliably Anticipatory Prices:</i> Futures prices tend to be highly reliable estimates of what should be expected on the basis of <i>contemporarily available information</i> concerning present and probable future demand and supply; price changes are mainly appropriate market responses to changes in information on supply and demand prospects (1934; 1949).	Futures prices are highly unreliable estimates of what should be expected on the basis of existing information; their changes are largely unwarranted. (A wholly unproved inference; accumulating evidence mainly supports the new concept.)
6. <i>Market-Balance Concept:</i> A significant tendency for futures prices to rise during the life of each future is not uniformly present in futures markets, and when it exists is to be attributed chiefly to lack of balance in the market (1960).	Aversion to risk-taking, leading to risk premiums, produces a general tendency toward "normal backwardation" in futures markets, statistically measurable as a tendency for the price of any future to be higher in the delivery month than several months earlier.

* Dates shown in parentheses are years in which the concepts may be said to have emerged. Where two dates are shown, the earlier one is the date of publication of evidence recognized as challenging the older concept; the later date, that of first-known publication of at least the substance of the new concept.

^a A statement of this concept was first prepared for publication by H. S. Irwin about 1946, but actual publication was delayed until 1954 (see below, pp. 435-36).

and conclude that such research can serve economics in the same way that Conant describes it as serving the natural sciences.

The practical question of economic usefulness of futures markets is only incidentally referred to in the present paper, inasmuch as our concern here is to trace the advance of economic understanding rather than to discuss the practical uses of such understanding. It will be readily observable, however, that the improved understanding contributed by each of the new concepts except the first, which bears only on the technical question of correct measurement, tends either toward refuting common criticisms of futures markets or toward indicating greater usefulness than has ordinarily been attributed to them, or both.

I. The Open-Contract Concept

First of the six new concepts to emerge, and a necessary precursor of much that was to follow, was the concept that the business of futures markets should be measured primarily in terms of volume of contracts outstanding—so-called “open contracts.” This was a revolutionary concept, carrying with it recognition that the traditional main function of markets, transfer of ownership, is not a significant function of a futures market. In futures markets there is little buying and selling in the usual sense, with its connotation of transfer of ownership. Instead, futures markets exist chiefly to facilitate the holding of contracts; the making and offsetting of those contracts, misleadingly called buying and selling,² is only incidental to the main function of such markets.

The revolutionary character of this concept was so little recognized at the outset that the concept was accepted in its original form without controversy,³ and without explicit record of who deserves credit for

² Futures contracts, used chiefly as purely financial rather than as merchandising contracts, are executed under terms that provide explicitly for settlement by financial transfer rather than by any transfer of commodity ownership (though allowing the latter as an alternative means of settlement). If the execution of such contracts went under an appropriately distinctive name instead of being called “buying and selling,” people would not so often think it a perversion of sound business practice that transfer of commodity ownership occurs only infrequently under those contracts. In fact, it is excessive forcing of settlement by transfer of commodity ownership, in connection with corners and squeezes, that is a perversion of the use of futures contracts.

³ This was probably because of the evident significance of open contracts for the theory of hedging, and because initial acceptance of the importance of open contracts did not require granting open contracts a central position in consideration of futures markets, such as they were eventually to command, but only granting them attention. Collection of the data on open contracts was indeed opposed by those who sought to avoid the expense entailed in supplying data, and even more vigorously opposed on the ground that the statistics of open contracts revealed information that, it was alleged, should not be made public. The latter contention, it should be noted, implied recognition of the pertinence of the data to study of market functioning.

the innovation. The concept emerged effectively about 1922 during consideration of what data should be collected by the newly-created Grain Futures Administration. Credit for it belongs chiefly, I think, to J. W. T. Duvel, who was shortly to become the first administrator of that federal agency, and during his long occupancy of that position gave research a prominent place in the work of that regulatory body.⁴

Directing attention to open contracts in the study of futures markets had an effect similar to that produced on the study of medicine and related science by Pasteur's discovery of bacteria; it led to study of the *causes* of phenomena, and thus toward true understanding, where previously only symptoms had been considered and understanding had been frustrated. And, incidentally, terms new to economics were required, such as "long position" and "short position" and "long hedging" and "short hedging."

The main fruits thus far of adoption of the open-contract concept have flowed from the fact that it led to quantitative study of hedging, which was obviously not significantly measurable in terms of trading statistics. It thus led directly to a new understanding of the parts played by hedging and speculation, respectively, in the origin and functioning of futures markets—a new understanding reflected in the hedging-market concept to be considered next; and it contributed significantly to emergence of the multipurpose concept of hedging. Studies of speculation have not benefited so much from the open-contract concept, partly at least because persistence of the mistaken idea that speculation is well measured by trading has considerably retarded study of speculation in terms of open contracts; but studies of the statistics of open contracts, as we shall see in the next section, have recently raised questions that bear especially on speculative behavior.

II. *The Hedging-Market Concept*

Futures markets have usually been regarded, in the past, as essentially *speculative* markets. Although they rather early won recognition as useful for hedging, their hedging use was treated as a fortunate by-product, neither necessary to the existence of such a market, nor

⁴ The decision to collect statistics of open contracts is recorded in [50, p. 691]. Preparation of the Federal Trade Commission's monumental *Report on the Grain Trade* was then in progress and economists of the Commission, promptly adopting the idea that open contracts should be studied, undertook compilation of open-contract data for some earlier years [51, Vol. 7, pp. 8-89, 124ff.] W. H. S. Stevens, who, with Francis Walker, was in general charge of the Federal Trade Commission inquiry, has told me that G. P. Watkins, of the Commission Staff, may have been responsible for the idea that statistics of open contracts should be collected; but the fact that Watkins, instead of presenting an argument of his own for use of open-contract statistics, quotes Duvel on the subject [51, Vol. 7, p. 134] leads me to think that principal credit belongs to Duvel.

very closely related quantitatively to the amount of speculation on the market. At Chicago, where dealings in forward contracts first took on the essential characteristics of a modern futures market, dealing in futures was initially regarded in the grain trade itself as a disreputable speculative business; for more than a decade the Chicago Board of Trade refused to allow such transactions in its quarters.⁵ The opinions of economists are reflected in familiar treatments of the theory of futures markets that begin by supposing the only participants in the market to be speculators.

The first step toward a radically altered view of futures markets came with the discovery of what might justly be called Irwin's Law. After statistics of open contracts had been collected by the Grain Futures Administration for only a few years, a staff member of that agency, H. S. Irwin, noted that the volume of open contracts varied seasonally in accordance with seasonal changes in the volume of commercial stocks subject to hedging [16]. Irwin was not then willing to conclude that speculation tended to enter and leave a market in direct response to variation in the amount of hedging, and sought explanation otherwise.⁶ Hoffman [11, pp. 33-41] later studied additional evidence on the correspondence between commercial stocks and open futures contracts, and found it observable in year-to-year variations as well as within the year. With the aid of statistics of hedging, available for the last three years of the period that he studied, he brought to light the fact that the net amount of hedging (short minus long), which he supposed was the hedging variable logically to be considered, did not always vary in close correspondence with commercial stocks.

Presently Irwin undertook a study of the origins of futures markets in butter and eggs, taking advantage of the fact that there were then people still alive who had witnessed the early stages of emergence of futures markets in those commodities. Verbal accounts by such people, supplemented by extensive study of contemporary published information, convinced Irwin that the prime incentive to emergence of those futures markets came from hedgers rather than from speculators. This conclusion, though consistent with the statistical evidence noted above, ran contrary to an established belief, and Irwin was unable to get publication for his original paper. By the time he resorted to private

⁵ Irwin [17, pp. 69ff] dates futures trading in Chicago from near the beginning of the 1850's, and my reading of Taylor's *History* [28] leads me to a similar conclusion. Dealings in futures were first admitted to the Chicago Board of Trade in 1865 [28, Vol. 1, p. 331].

⁶ His suggestion was that the seasonal increase in amount of speculative buying of wheat at harvest time "arises chiefly from the wheat-growing sections tributary to each market, and that it is done largely when the wheat is sold," and he was able to cite some evidence in support of the hypothesis [16, p. 45]; but the hypothesis subsequently proved inadequate to account for the observed facts.

publication in 1954, in expanded form [17], the present writer had profited from a reading of Irwin's original manuscript in 1946, had found that his conclusion conformed with a great and varied mass of other information, and had argued that futures markets ought not to be regarded as primarily speculative, but as primarily hedging markets [40, pp. 318-19]⁷ [42].

The statistical data on hedging and speculation, as they accumulated, produced evidence that the relationship was not a simple one connecting speculation with net hedging, as it had seemed natural to assume. Statistical analysis presently revealed that long hedging serves only in part to offset short hedging, and in part creates a need for short speculation. With this circumstance taken into account, the amount of speculation was shown to vary in much closer correspondence with the amount of hedging than had been evident previously. Chart 1 illustrates the correspondence found for variations through time in one market.^{7a} A similarly close correspondence was found for variations between markets, using five-year averages [48, p. 198].

III. *The Multipurpose Concept of Hedging*

According to the traditional concept, hedging consists in matching one risk with an opposing risk, and hedging in futures is effective because changes in spot prices of a commodity tend to be accompanied by like changes in the futures price. The fact that hedging usually involves more than risk avoidance has long been known to hedgers themselves and to some economists. Wiese, a businessman, seems to have been the first person to criticize the traditional concept as seriously misleading [32, p. 113]. An attempt by Graf [8] to test the efficacy of hedging produced the first evidence which was recognized

⁷ Inadvertent omission from that paper of due credit to Irwin was corrected in [44].

^{7a} Further research seeking interpretation of the evidence in Chart 1 has led the author to two conclusions that deserve to be noted, though they cannot be elaborated, here. The estimation procedure used to arrive at the data for the chart assumes fairly complete reporting of hedging, both short and long, and in the absence of that condition tends to produce a spurious degree of stability in the ratio between estimated amounts of long speculation and of short hedging, hence to exaggerate the closeness of response of speculation to hedging. The condition for reliability of the estimates in this respect is probably better met for wheat than for any other commodity, and is met best in periods when the amount of short hedging is large. Secondly, theoretical study of the mechanism by which one may suppose that the adjustment between amounts of speculation and of hedging is accomplished seems to make the concept of incomplete balancing between short and long hedging appropriate theoretically only in connection with comparatively long-time adjustments; its use in the accompanying chart to exhibit evidence on short-time adjustment is then to be regarded as only a graphic device. Statistical analysis of the data on lines that now seem theoretically appropriate have shown a degree of correspondence between estimated amounts of speculation and of hedging broadly similar to that indicated in the chart above.

CHART 1. EVIDENCE THAT CHANGES IN AMOUNT OF LONG SPECULATION OCCURRED CHIEFLY IN RESPONSE TO CHANGES IN AMOUNT OF UNBALANCED SHORT HEDGING, WHEAT, JULY 1956-JUNE 1959* (million bushels)

* Data from [48, p. 208] and like data for month-ends. Unbalanced 'short hedging' is the total of open short-hedging contracts, less an appropriate fraction of open long-hedging contracts.

as showing that the simple risk-avoidance concept was seriously misleading to economists [41, pp. 544-45].

Quantitative studies, perhaps surprisingly, have contributed more to understanding of hedging than have verbal inquiries concerning business motivation. Particularly noteworthy among these were studies of the quantitative relation between hedged stockholding and market "carrying charges," which brought recognition that much hedging was done to assure profits, not merely to avoid risk [41, pp. 556-57]; studies of flour-mill practice in maintaining a rough inventory balance involving the three items, physical stocks, forward merchandising contracts, and futures contracts [41, p. 549], which produced evidence that risk avoidance was inadequate as an explanation of flour-mill hedging;⁸

⁸ This led presently to at least a partial explanation of the ineffectiveness of verbal inquiry into the motivation of hedging: after conclusions concerning the reasons for mill hedging had been published, a mill manager, asked why millers say that they hedge to avoid risk instead of giving the real reasons, promptly replied, "Because it is hard to explain the real reasons to a person who doesn't understand the milling business."

and statistical inquiries intended to test the efficacy of hedging, which as noted above, produced demonstrably false conclusions explicable only on the ground that acceptance of the pure risk-avoidance concept of hedging had led to the making of a test that grossly misrepresented the effects of hedging as actually practiced. And even nonquantitative inquiry has been sufficient to establish that some hedging is practiced with neither the intent nor the effect of reducing risk.

Business hedging is done for a variety of reasons, which differ according to circumstances. Consequently it is necessary to recognize the existence of several different categories of hedging and to consider them separately with respect to business purposes and economic effects.

1. *Carrying-charge hedging* is done in connection with the holding of commodity stocks for direct profit from storage (rather than merely to facilitate the operation of a producing or merchandising business). Whereas the traditional concept implies that hedging is merely a collateral operation that, in this application, would influence the stockholding only through making it a less risky business, the main effect of carrying-charge hedging is to transform the operation from one that seeks profit by anticipating changes in price level to one that seeks profit from anticipating changes in price relations. Whether a businessman regards such a transformation of the operation as desirable or not depends less on differences between inherent riskiness of the two sorts of operation than on whether he personally feels better able to predict changes in price levels or changes in price relationships. In general, producers of a commodity and those who use it as a raw material, when they undertake storage for profit, prefer to seek the profit by anticipating changes in price level, and therefore either do not hedge, or hedge selectively (see below): it is chiefly merchants, whose merchandising business requires close attention to price differences according to grade, quality, and location, who choose to seek storage profits by anticipating changes in price relations, thus using to best advantage their special knowledge concerning price relations.

Whereas the traditional hedging concept represents the hedger as thinking in terms of possible loss from his stockholding being offset by gain on the futures contracts held as a hedge, the carrying-charge hedger thinks rather in terms of change in "basis"—that is, change in the spot-future price relation. And the decision that he makes is not primarily whether to hedge or not, but whether to store or not.⁹

⁹In consequence, the term "carrying-charge hedging" tends to be used sometimes to designate the combined operation of storage and hedging for profit. In trade usage the combined operation is sometimes called "earning the carrying charge." It is an operation not properly divisible into two parts, for without the hedging the storage becomes a quite different operation, from the business point of view, requiring use of different in-

2. *Operational hedging* is done chiefly to facilitate operations involved in a merchandising or processing business. It normally entails the placing and "lifting" of hedges in such quick succession that expectable changes in the spot-future price relation over the interval can be largely ignored; and it is this fact which chiefly distinguishes operational hedging from carrying-charge hedging. Because the intervals over which individual operational hedges are carried tend to be short, the amount of risk reduction accomplished tends to be small—quite insufficient to explain the observed prevalence of operational hedging. Besides reducing risk, to an extent that the hedger may or may not consider significantly advantageous, it leads to economies through simplifying business decisions and allowing operations to proceed more steadily than otherwise.

Illustrations of the principal advantages of operational hedging may well be drawn from flour-milling because it was study of flour-mill hedging that first led to recognition of the special characteristics of operational hedging. In this industry buying and selling decisions are facilitated because it is easier for the mill buyer to judge prices on particular lots of wheat in terms of their relation to other wheat prices than in terms of absolute level. And similarly it is easier to judge the price offered by a potential flour buyer in relation to a present wheat price than in relation to the price that may have to be paid on a later wheat purchase. When hedging is practiced, it becomes logical to make these buying and selling judgments on the easier basis. And wheat buying in particular can be carried on more steadily than otherwise because the basis is subject to less fluctuation than is the price.

These business advantages of operational hedging, however, depend on the existence of a high correlation between changes in spot prices and changes in futures prices over short intervals—day to day and even within the day. Such correlation of short-interval price changes is not always present, and in its absence there tends to be little operational hedging even though the broader correspondence between changes in spot and futures prices be close enough to permit effective risk reduction through hedging. Flour mills west of the Rocky Mountains in the United States usually do not hedge, because spot wheat prices in that area do not move in sufficiently close day-to-day correspondence with futures prices in mid-western markets to permit satisfactory operational hedging.¹⁰

formation to conduct it successfully, and leading often to a different choice of the intervals over which storage is undertaken.

¹⁰ Mills in the area tributary to Seattle make little use of the alternative of hedging in the Seattle futures market because that is a very "thin" market, with consequent high costs of hedging.

3. *Selective hedging* is the hedging of commodity stocks under a practice of hedging or not hedging according to price expectations. Because the stocks are hedged when a price decline is expected, the purpose of the hedging is not risk avoidance, in the strict sense, but avoidance of loss. Published studies of hedging in the grain trade of the United States have indicated the presence of selectivity in hedging, through reports that hedging was done "to some extent" or "occasionally," chiefly among country elevators [51, Vol. 1, pp. 213, 214] [22]. Efforts on the part of such small firms to gain profits from appraisal of price prospects, as is implied by selectivity in hedging, appear ordinarily ill-advised. But personal inquiry among large and well-managed firms in the grain trade has revealed that, though hedging is their standard practice in most parts of the country, they sometimes hedge incompletely. To the extent that they allow circumstances in individual instances to influence the decision whether to hedge unsold stocks or not, they hedge selectively. Outside the grain and cotton trades, which appear to be the principal ones in which routine hedging is accepted as standard practice in most parts of the country, selectivity in hedging is so common as to suggest that in a considerable number of futures markets the greater part of the short hedging done may be selective.¹¹

When hedging is done selectively, the advantage of the hedging to the individual firm may often (perhaps usually) be measured approximately by the amount of loss avoided directly by the hedging. Though curtailment of the amount of unsold stocks is an alternative means of restricting loss at a time of expected price decline, it is a means that few firms are able to use freely, owing to operating needs for carrying stocks. Selective hedging almost inevitably yields large advantages to any merchandising or processing firm that is able to anticipate price changes reasonably well. From an economic standpoint selective hedging deserves appraisal as simply one aspect of the use of futures markets

¹¹ The prevalence of selectivity in hedging on the smaller futures markets has at least two possible explanations. One, attributing smallness of the futures market to lack of speculative interest in the commodity, would explain the prevalence of selective hedging on the ground that the market lacks enough speculation to support routine hedging by any large proportion of potential hedgers, thus discouraging the development of much operational hedging and making storage for profit from expected price increases, with hedging when price decrease is expected, seem more profitable than carrying-charge hedging.

Another possibility is that the smaller futures markets have as little business as they do because of circumstances apart from the futures market that lead potential hedgers to prefer to rely on price judgments rather than on judgments concerning spot-future price relationships. Recognition of the multiple purposes of hedging should open the way to research that would give better evidence than we now have to explain why some futures markets are as little used as they are.

as a means by which handlers of a commodity increase the efficiency of their participation in the price-forming process, instead of largely withdrawing from such participation, as they do when they practice routine carrying-charge or operational hedging. Futures markets that receive a large amount of selective hedging tend also to have a considerable amount of "speculation" by handlers of the commodity. Inasmuch as selective hedging must come chiefly from those handlers of the commodity who commonly hold substantial stocks, and who therefore take a long position by merely refraining from hedging, it is to be presumed that the "speculative" use of futures by handlers of the commodity comes mainly from dealers whose business requires relatively little holding of physical stocks.

4. *Anticipatory hedging*, which also is ordinarily guided by price expectations, differs from selective hedging in that the hedging contract is not matched by either an equivalent stock of goods or a formal merchandising commitment that it may be said to offset. It takes either of two principal forms: (a) purchase contracts in futures acquired by processors (or manufacturers) to cover raw material "requirements";¹² or (b) sales contracts in futures by producers, made in advance of the completion of production. In either of these forms the anticipatory hedge serves as a temporary substitute for a merchandising contract that will be made later. In the one case it serves as a substitute for immediate purchase of the raw material on a merchandising contract; in the other case it serves as a substitute for a forward sale of the specific goods that are in course of production. The purpose of the hedge may be said to be to take advantage of the current price; or, bearing in mind the usual availability of an alternative means of doing that, merely to gain some advantage in convenience or economy through the choice made between alternatives.

The best presently available statistics that give some indication of the prevalence of anticipatory hedging are those on long hedging, which reflect also the similarly motivated forward merchandising contracts, to the extent that they are hedged, that many processors use as a means of anticipating requirements. Nearly all long hedging consists either of anticipatory hedging or of hedging of forward merchandising contracts (often called unfilled orders) that are themselves anticipatory in the same sense as the anticipatory hedging. On the latest date (September 28, 1956) for which there are statistics of open contracts in cotton that allow accurately segregating "matching" contracts from those that were purely speculative, long hedging contracts

¹² Such use of futures contracts was first given legal status as hedging under the Commodity Exchange Act by an amendment enacted in 1956 (70 Stat. 630).

totaled 1,001 thousand bales, as compared with 268 thousand bales of long speculative contracts [48, p. 192]. This was at a time when the amount of short hedges to be carried was near its peak.

5. Pure *risk-avoidance hedging*, though unimportant or virtually nonexistent in modern business practice, may have played a significant part in the early history of futures markets. In the absence of records concerning the uniformity of hedging by firms using the early futures markets, however, it is impossible to know to what extent early hedging, described as done "to reduce risk," actually had that purpose in the strict sense, or was selective hedging, done to avoid incurring loss from an expected price decline.

Recognition of the fact that hedging is done for a variety of purposes requires defining hedging otherwise than has been customary. The verb "to hedge," in the sense of avoidance or shelter, has no general connotation of avoidance especially of risk; the gambling practice of hedging bets is perhaps as often used to offset an expected loss as to reduce risk in the strict sense; and there is in any case no good reason why the word "hedging" as applied to business practices should be restricted to operations such as gamblers call hedging. For present purposes we need to define only hedging in futures. All the uses of futures that are commonly called "hedging" will be comprised, and all other uses excluded, if we characterize hedging as the use of futures contracts as a temporary substitute for a merchandising contract that is to be made later.¹³

Inclusion as hedging of the practices characterized above as selective hedging and anticipatory hedging requires either regarding hedging as sometimes closely akin to speculation,¹⁴ or defining speculation otherwise than has been usual in economics texts. In ordinary usage and in much economic discussion the word "speculation" refers to buying and selling (or, more accurately, holding) property purely for the sake of gain from price change, and not merely as an incident to the normal conduct of a producing or merchandising business or of investment. So it is usual to distinguish between speculation in securities and the holding of securities for capital gain; many people tend to think it a strained use of the term when speculation in commodities

¹³ This definition was originally given with slightly different wording in [41, p. 560].

¹⁴ For administrative purposes of distinguishing between anticipatory hedging of raw material requirements and speculation, the Commodity Exchange Act, as amended in 1956, restricts such anticipatory hedging to "... an amount of such commodity the purchase of which for future delivery shall not exceed such person's unfilled anticipated requirements for processing or manufacturing during a specified operating period not in excess of one year: *Provided*, that such purchase is made and liquidated in an orderly manner and in accordance with sound commercial practice . . ." In effect this provision draws the same line between hedging and speculation as does the definition of speculation given in the next footnote.

is defined to include the holding by a farmer of part of his crop for a few weeks after harvest; and business purchasing agents object to being said to speculate when they seek to time their buying, within reasonable limits, in accordance with their judgment of price prospects. If speculation is defined in accordance with ordinary usage of the term, hedging and speculation in futures are always distinguishable.¹⁵

IV. *The Price-of-Storage Concept*

Though much uncertainty has existed about the relations of futures prices to spot prices, one proposition long stood unquestioned: there seemed to be no generally necessary relationship between prices that depend on the abundance or scarcity of currently available supplies—spot prices for example—and prices on futures contracts applying to supplies from a subsequent harvest. To be more specific, it was regarded as clear that, in the presence of a current relative scarcity of wheat, prospects for an abundant harvest in the following summer would have no significant bearing on prices paid for existing supplies.

Statistical studies published in 1933, supplemented by further evidence later, showed this belief to be untrue.¹⁶ What happens in fact is that any change in price of a distant, new-crop, wheat future tends to be accompanied by an equal change in prices paid for wheat from currently available supplies.¹⁷ A comparative shortage of currently available supplies of wheat has its direct effect on the spread between

¹⁵ For this purpose, speculation in commodities may be defined as the holding of a net long or a net short position, for gain, and not as a normal incident to operating a producing, merchandising, or processing business. The reference to net position in this definition, proposed in [48, p. 187], serves to exclude arbitrage from speculation. Though the two have something in common, they need to be distinguished, and that is done more conveniently by defining speculation to exclude arbitrage than by adopting a new term to mean "speculation other than arbitrage."

¹⁶ See especially [33, pp. 188-203] [34, pp. 199-205]. These studies, dealing with prices in a single exporting country, were later supplemented by a similar inquiry into price behavior in the major import market for the same commodity [12]. Comparisons of behavior between these two widely differing sorts of markets helped to indicate which behavior characteristics were special to a particular sort of market and which were more generally observable. In both markets prices of the near future responded sensitively to distant price expectations, but the influences that bore particularly on the price of the near future, causing its price movement to diverge more or less from that of the distant future, were appreciably different in the two markets [12, esp. pp. 102-5, 110-26, 136-38].

¹⁷ This statement is true also for most other commodities that have futures markets, but is inapplicable to prices of a commodity, like potatoes or onions, that is incapable of economical interseasonal storage. Gray [9, pp. 305ff] has noted that it seems not to apply to coffee in the United States. Interpretation of his evidence requires recognition that the "price of storage," reflected in the price difference between futures for different dates, is dependent on the *expected* level of stocks during the interval between those dates, and that such expectations regarding future domestic stocks of an imported commodity may be affected by some of the same circumstances that influence the price of a distant future.

the spot price and the futures price, causing wheat from current supplies to sell at a premium over the expected future price of new-crop wheat. In effect, then, the spot price is determined as the sum of the futures price, dependent primarily on expectations, plus a premium dependent on the shortage of currently available supplies.

These observed facts of price behavior were contrary to what was logically deducible from the prevalent concept. Introduction of the concept that intertemporal price differences constitute prices of stor-

CHART 2. ACTUAL COURSE OF NEW-CROP AND OLD-CROP CORN FUTURES AND "PREDICTED" COURSE OF OLD-CROP FUTURE, JUNE-AUGUST 1947*

* "Predicted" course derived by traditional theory from initial price of old-crop future and actual course of new-crop future.

age [39] provided a key to understanding the observed facts and served in effect as a summary of the facts. The most significant of these facts from the standpoint of economic theory is that spot prices of storable commodities tend to respond sensitively to changes in distant expectations. Chart 2 illustrates this tendency. The great price advance that it shows in the new-crop December corn future, owing to crop deterioration in July and August 1947, was accompanied throughout by a like advance in the price of the old-crop September future. If the traditional concept of price dependence on currently available supplies were valid, the price of the September future, comparatively high in June because of shortage of old-crop corn supplies,

would have held fairly steady during June and early July, until deterioration in new-crop prospects caused the December future to rise to and above the price of the September future, and thereafter would have followed the course of the December future, but at a slightly lower level.

The main reason for listing the price-of-storage concept as marking a significant step in the advance of economic science is that it seems capable of displacing the belief that spot prices are commonly little affected by changes in distant expectations. That opinion is not founded on any factual observation, but has its basis in an assumption embedded in the conventional exposition of price formation, an exposition that is ordinarily taken to mean that "supply," as a determinant of spot price, means currently available physical supplies. A belief so derived will not be corrected merely by citing observational evidence to the contrary,¹⁸ but only through providing an evidently valid conceptual scheme that requires bringing expectations into account as determinants of spot prices.¹⁹

V. The Concept of Reliably Anticipatory Prices

Prices on futures markets (and also spot prices of many commodities and prices on the stock market) are observed to change frequently and in an apparently erratic manner. These price changes have traditionally been conceived to be in large part random fluctuations, with some degree of cyclicity impressed upon them. Evidence of the substantial falsity of that concept has long been widely known, but the

¹⁸ One evidence of this fact appears in the short-lived controversy that developed between the present author and Roland P. Vaile [36] [31] [37].

¹⁹ Two recent expositions by leading economists [25] [14] that may seem to ignore or reject the price-of-storage concept were not so intended. They sought to present a theory of price formation under conditions of certainty, leaving the effects of uncertainty to be treated in later elaboration of the theory, and assumed that under conditions of certainty, stocks would be carried only in the expectation of a direct return for storage equal to the "costs" of storage, the latter treated as being invariant with respect to the quantity to be stored. In fact, however, the observed willingness of dealers and processors to carry stocks of wheat, for example, at the end of a crop year for a negative price of storage arises only in small part from the presence of uncertainty. Each of three other considerations has more influence, namely: costs of abnormal acceleration of the movement of new-crop wheat from harvest field to mill rollers; temporal dispersion of harvest times; and geographical dispersion of flour mills among areas with different harvest times.

If convenience of exposition is well served by proceeding in two stages, the first of which assumes that stocks will fall to zero in the absence of an expected return from storage equal to the full "costs" of storage, the simplifying assumptions involved at the first stage should include instantaneous harvest of the entire crop, and costs of movement from producer to consumer that are invariant with respect to rate of movement. The supposed advantage of the two-stage exposition, with price of storage ignored at the first stage, will be found illusory, I think, when economists have fully assimilated the price-of-storage concept.

conflict between concept and evidence could be visible only to a person who was well aware of the distinction between random variation and random walk.²⁰ The so-called "fluctuations" of futures prices, of some other commodity prices, and of stock prices, exhibit close approximations to pure random walk.²¹

When attention was drawn to that characteristic of certain prices, about a quarter-century ago, the discovery aroused no comment and no apparent lasting interest on the part of either statisticians or economists.²² It was a factual observation that carried no economic meaning, even to people who understood the technical distinction between random variation and random walk. But presently the economic meaning of the discovery was found: Pure random walk in a futures price is the price behavior that would result from perfect functioning of a futures market, the perfect futures market being defined as one in which the market price would constitute at all times the best estimate that could be made, from currently available information, of what the price would be at the delivery date of the futures contracts [38, p. 160].

The observation that the behavior of futures prices corresponded

²⁰ A familiar illustration of random variation is the variation in number of spots that turn up when a pair of "true" dice is thrown after being thoroughly shaken each time. By proceeding from that illustration, one may illustrate random walk by drawing on a chart a line that moves forward one space for each throw of the pair of dice, and up or down by a number of units equal to the number of spots minus seven (seven being the "expected" number of spots on each throw). Randomness, in the statistical sense, however, does not necessarily involve absence of known causes for the events designated as random, but only that individual events are unpredictable from knowledge of previous events in the series. Thus prices may change from known causes, but if the changes are unpredictable from any knowledge of previous prices and price changes, as the changes in the curve drawn on the basis of dice-throwing are unpredictable from the previous course of the curve, the price series exhibits random walk.

²¹ This appears to be true of commodity prices only within time spans not longer than about one year, but true of stock prices over much longer time spans.

²² The two early papers on the subject were complementary in nature. Mine [35] stressed the difference between random variation and random walk, and presented a 2400-term random-walk series as a device both for illustrating the close conformity of actual price series with the random-walk model and for testing such evidences of departure from that model as might be observed. Cowles and Jones [6] gave a great amount of statistical evidence in the course of exploring the question whether appreciable non-randomness of stock-price changes might be found at some difference-intervals though not at others. See also [7], in which Cowles gave revised results that eliminated the effects of inadvertent use in [6] of one index number series that had employed undesirable averaging. Kendall [19], much later and in apparent ignorance of earlier work, provided a test of the hypothesis that nonrandomness of change might be revealed by serial correlations of orders higher than the first, using a constant difference-interval. The only substantial indication of significant serial correlation that Kendall found was in a first-order coefficient for cotton prices; and that, as shown in [49], was a correlation attributable to averaging in the construction of the cotton price series used, hence invalid as evidence that cotton prices showed any departure from random walk.

closely to random walk thus led to the economic concept that futures prices are *reliably* anticipatory; that is, that they represent close approximations to the best possible current appraisals of prospects for the future [46]. Conceiving the "fluctuations"²³ of futures prices to be mainly appropriate responses to valid changes in expectations produces a great change in thought regarding them, as compared with regarding the price movements as mainly lacking economic justification.

Further discussion of the evidence that futures prices are reliably anticipatory requires dealing with a problem of the meaning of "reliability" in this context. Custom has established the idea that reliability of uncertain expectations is to be tested by correspondence between the expectation and the event, but we need here to consider reliability of expectations in the sense of correspondence between the actual expectation and what ought to be expected in the light of available information. At times, in order to avoid confusion, I shall speak of the latter as *anticipatory reliability*.

The inference, from evidence of approximate randomness of change in futures prices, that those prices have a high degree of anticipatory reliability was initially open to serious question on the ground of suspicion that the price changes were in fact much less nearly random than early statistical tests seemed to indicate. Randomness of walk in a statistical series is not a specific characteristic detectable by any one specific test, but a term that designates absence of any systematic characteristic—absence of any sort of "structure," as Cowles and Jones aptly expressed it [6]. Because the kinds of structure commonly believed present in futures prices and in stock prices are trends and cycles (in a somewhat loose usage of those terms), those kinds of structure were the first looked for as evidence of nonrandomness; and the statistical tests used were familiar ones that had been proved appropriate for revealing structure of those sorts in other data, namely, tests for the presence of simple autocorrelation.²⁴ Failure of those tests to reveal an appreciable degree of structure in futures prices, however, left open the question whether other sorts of structure might not be present.

Two principal lines of inquiry have been followed in the search for kinds of structure that would not be revealed by simple autocorrela-

²³ The quotation marks are repeated here as a reminder that the price changes referred to do not have a dominantly wave-like character such as tends to be implied by calling them fluctuations.

²⁴ By "simple" autocorrelation I mean autocorrelation in the sense in which that term has been commonly understood, namely correlation between items uniformly spaced in time, or in the case of correlation of first differences, differences taken over uniform time intervals, uniformly spaced. It would be reasonable to regard any form of structure in a time series as involving some form of autocorrelation.

tion analysis, or equivalent methods. One line of inquiry has reasoned that the price movements to be correlated should be selected according to magnitude of the movement, without regard to the time taken to accomplish a movement of that amount. By proceeding thus, Alexander [1] has recently shown the presence of an appreciable tendency for stock-price movements of 5 per cent or more (in an index of industrial stocks) to be followed by further price movement in the same direction.²⁵ Houthakker [15, p. 166] has published results that, though calculated and presented from a point of view different from that of Alexander, can be interpreted as indicating presence of the same sort of tendency in prices of wheat and corn futures that Alexander found in the stock-price index.

Another line of attack involved the design of a new type of statistical test that appeared capable of revealing any such tendency toward continuity of movement in futures prices, if it were present, and also capable of revealing a tendency for a price movement in one direction to be followed by an opposite movement (reaction), but without uniformity in timing of the reaction, which might sometimes be prompt and sometimes considerably delayed. A test devised for this purpose promptly yielded statistically significant evidence of structure in futures prices [3], but further research was required to determine the kind of structure that was indicated.²⁶ The principal component of the structure was presently identified as such as would be produced by a tendency for the price effects of new market information to be partially dispersed over a considerable time interval rather than all concentrated within the day on which the new information became available [45] [46]. Later it was found possible to determine approximately the fraction of the average price effect that was so dispersed and the average time span of dispersal, and also to derive similar approximations for a secondary sort of structure, involving excessive price

²⁵ Price moves of 5 per cent were the smallest ones considered by Alexander. In an earlier work of mine, I applied the same principle as did Alexander to study of very small price movements of futures, and found in the smallest movements, of which there may be several hundred within a day, a substantial tendency to negative (rather than positive) correlation [43, p. 11]. Like Alexander, I found that the evidence of structure that was revealed by considering movements of given size tended to become invisible under consideration of movements over given time intervals.

Analysis of correlation by movement size is laborious (my work along that line was done before electronic computers became widely available), and partly for that reason I turned to another approach, described below, that seemed to hold as good, or perhaps better, possibilities of uncovering the presence of obscure sorts of structure in price "fluctuations."

²⁶ The difficulty in identifying the kind of structure indicated arose partly from inherent difficulty in predicting how a new sort of test, designed to be responsive to a variety of different sorts of structure, would respond to particular sorts of structure; but that inherent difficulty was complicated by the fact that the kind of structure indicated was of an unexpected sort.

movement on individual days, with reaction dispersed on the average over a period of a few adjacent days [20]. The latter, rather weak, tendency was found to be associated with relatively small price movements, and the former tendency, mainly with the larger price movements.

The results produced by the two lines of inquiry summarized above appear at present to be entirely consistent. Those from the first approach are the more readily interpretable, up to a certain point. Those from the second approach lend themselves the more readily to appraisal of the degree of anticipatory reliability that can be attributed to futures prices, or to such other prices as deserve similar appraisal. The most notable feature of the evidence from these two lines of inquiry, however, is not quantitative but qualitative. Each has indicated that the main kind of structure present in anticipatory (speculative) prices is roughly the opposite of that which has been chiefly charged against such prices. Whereas these prices commonly have been thought to "fluctuate" too much, showing large movements up or down that tended to be followed by reaction, in a roughly wave-like pattern, the evidence is that reaction is common only from very small movements, of short duration, which may be regarded as caused by minor accidental disturbances; that in the main the imperfection of behavior in futures markets takes the form of retardation of price response to information that warrants price change. This retardation, being an effect similar to that of shock-absorbers on an automobile, tends toward the avoidance of excessive initial movement and subsequent reaction.

The concept that futures prices are reliably anticipatory, in the full sense of that term, evidently does not correspond wholly to the facts. In that respect it is like the concept that gases are perfectly elastic, as represented by Boyle's Law, $VP = C$. If the economic concept of anticipatory reliability of futures prices is subject to a good deal more supplementary qualification than is the physical concept of perfect elasticity of gases, it appears nevertheless to correspond more closely to full reality than does any other concept that might be used for fairly simple representation of the main facts. It avoids the gross misrepresentation involved in the concept that the variations in futures prices are in large part unwarranted, wave-like, fluctuations; and its own misrepresentation is of a sort that is inevitable in a concept that, for the sake of simplicity, must fall short of representing the full facts.

VI. *Risk Premiums vs. the Market-Balance Concept*

The concept that risk-bearing commands a reward has been applied at several related points in the theory of futures markets, but has re-

cently attracted attention principally in connection with discussion of J. M. Keynes' "theory of normal backwardation." The market-balance concept, recently proposed by Gray [9] [10] as a substitute for the risk-premium concept in that context, has been advanced on the basis of evidence that may be thought inconclusive,²⁷ and has been applied only to explaining differences in seasonal trends²⁸ of futures prices in different markets—not obviously a matter of great importance. The reasons for nevertheless discussing the market-balance concept in the company of the better-proved and more demonstrably fruitful concepts discussed previously are, first, that the grounds for considering the merits of the market-balance concept are stronger than appears from the statistical evidence alone; and secondly, that there is evident need for taking other considerations into account, along with risk, at several points in the theory of futures markets where the tendency has been to consider only the risk aspect.

The earlier studies that sought to test Keynes' theory of normal backwardation took seasonal trend in futures prices to be a measure of risk premium (as Keynes apparently had done), and focused on the question whether the statistics gave evidence of a tendency to such seasonal trend or not. Telser at first denied that they did [29], whereas Houthakker [13] [15] and Cootner [5] found evidence of seasonal trends consistent with the Keynesian hypothesis. Gray, meanwhile, had been making studies of some of the smaller futures markets, which had previously received little attention from economists, and was thus led to put together the pertinent evidence for a considerable number of different markets, large and small. The diversity in magnitude, and even in direction, of apparent seasonal trend that he found among the various markets appeared to him not explainable on the basis of differences between risk premiums in different markets [10, p. 258], whereas the differences did appear explainable on other grounds that could be comprised by the term "market balance." The term was suggested by the evidence that the differences in seasonal trend were largely associated with differences between markets in amount of speculation relative to hedging—or, more strictly, relative to the potential amounts of hedging, inasmuch as a shortage of specu-

²⁷ The purely statistical evidence in [10, p. 257], for example, did not include a specific test of the hypothesis that the observed variation among apparent seasonal trends might be explainable as consistent with existence of a uniform tendency toward positive seasonal trend in all the markets and periods considered.

²⁸ I speak of "seasonal trends" rather than "bias," which has been the term more commonly used, because it designates what is actually measured, and then interpreted as evidence of bias; and I mean the term to comprise trends measured with respect to some pertinent seasonal variable such as Cootner [5, pp. 400-1] has suggested should be used, as well as trends measured with respect to calendar dates.

lation in a futures market must restrict the amount of hedging actually done.

The market-balance concept thus emerged because examination of a wider range of observational data than had been considered before posed a new question for answer. Viewed as bearing only on the original question—whether futures prices tend to show an upward seasonal trend—the new data could be interpreted as supporting an affirmative answer, in agreement with the general tenor of previous evidence; but the new data posed also the question of how to account for the occurrence of seasonal trends that in some markets and circumstances appeared to be significantly positive, and in others, significantly negative. The answer that was suggested, in the form of the market-balance concept, does not require rejecting the risk-premium concept, but regarding it as providing at best only a partial explanation of the tendencies to seasonal trend observable in futures prices.

Speculators' earnings have received significant direct study only by Stewart [27], and his inquiry, based on detailed records for nearly 9,000 speculators in grain futures, and covering a time period of nine years, was singularly unproductive of positive conclusions. Such unproductiveness in a large-scale investigation by an able economist skilled in statistical analysis and with a wealth of data at his command must indicate need for reconsidering prevalent economic ideas about the bases of speculative profits, which Stewart sought to explore. The "sample" of speculators that he dealt with showed a strong over-all tendency for them to incur losses, and though many among them gained profits, Stewart was unable to find an objective characteristic by which to classify speculators into groups with appreciably different profit experience.

If speculation be regarded as a skilled occupation (not mere risk-taking), in which the making of profits depends both on special skills and on continuously maintained knowledge of current economic conditions and prospects relevant to prices of particular commodities, Stewart's results become understandable. He had no information by which to classify speculators according to special speculative skills, or according to the amount and quality of their pertinent knowledge; hence his study could throw no direct light on the relations of speculative rewards either to special speculative skills or to amounts of pertinent economic information that they used.²⁹

In order that speculation should contribute to economically desirable price formation, speculators must keep well informed concerning

²⁹ The over-all tendency toward losses by the speculators in Stewart's sample must be attributed chiefly to lack of full representativeness of the sample; it included relatively few, if any, professional speculators, and may have been unrepresentative otherwise.

the pertinent economic facts, and must be able to appraise those facts properly. The evidence considered earlier that futures prices are reliably anticipatory, to a fairly high degree, indicates that a large proportion of speculation in futures markets has been based on sound information, properly appraised. Such speculation deserves to command a wage, and that fact is ignored when the returns from speculation are viewed solely as a reward for risk-bearing.

Data published by the Commodity Exchange Authority in recent years concerning some of the smaller futures markets have revealed that much of what is classed by the CEA as speculation in them comes from persons and firms dealing in the commodity, such as are ordinarily expected to be hedgers.³⁰ If one accepts the argument that speculation should be defined as suggested earlier (footnote 15) this raises the question whether a considerable part of the contract holdings that have been classed as "speculative," in those markets, might not more properly be treated as anticipatory hedging. In any case the evidence reveals that, for those commodities, the futures markets have served in important degree to allow dealers in the commodity to exercise their price-forming function more freely than they otherwise could. In the absence of a futures market, price formation is almost wholly in the hands of dealers (using that term to comprise all handlers of the commodity); and many of them must exercise that function under the handicap that their need to accumulate stocks in order to maintain their position as merchandisers may force them to act in support of a price that they regard as too high, or obstacles to stock accumulation at a given time may bar effective market expression of an opinion that the current price is unduly low.³¹ The presence of a futures market permits dealers to exercise price judgment without such restraints. The dealer who must accumulate stocks at a certain time for merchandising reasons may sell futures in equivalent amount and thus

³⁰ Such data appear in [26, p. 22], and subsequently in a number of CEA "surveys" for several markets and dates.

³¹ Particularly clear examples are afforded by the onion market, which is one of those in which a large proportion of the futures contracts classed as speculative was found to be held by dealers in the commodity [47, p. 7]. Onions from the late summer crop, which are stored for use over a period extending into April, are sold by growers to "country shippers," who store them. In order to maintain his competitive position as a dealer, the country shipper must buy when growers want to sell, and he is thus severely limited in opportunity to adjust his stock-holding in accordance with expectations of price change. Country shippers sell in turn to "dealers" in the large cities, who cannot economically accumulate large stocks because refrigerated storage, on which they would ordinarily need to rely, is much more expensive than "common storage" in the cold climates where most of the onions are produced. Consequently the city dealer, who may be better informed about the nationwide supply and demand situation for onions than most country shippers, and financially better able to carry risks of price change, is handicapped in expressing his price opinions through adjustment of stock-holdings.

avoid exerting a price-supporting influence when he expects a price decline; and the dealer who expects a price advance, but cannot well accumulate physical stocks of the commodity at the time, can buy and hold futures instead.

Thus the introduction of a futures market could result in substantially improved price behavior even though the futures market were used only by dealers in the commodity, the better price behavior being attributable to the opportunity given dealers to exert price influence strictly in accordance with price judgment instead of exerting price influence, or refraining from doing so, largely in response to immediate

FIGURE 1

merchandising or processing needs. Existence of a futures market may tend toward better support of prices during rapid marketing of a crop shortly after harvest, not primarily because speculators demand a lower risk premium than do dealers (if that be true), but chiefly because the futures market allows stocks to be "carried" either as physical stocks held unhedged or through the holding of long futures contracts that offset short hedging. This tends to change the balance of the market in the sense of the market-balance concept.

Because potential carriers of stocks have differing opinions regarding the price at which they can afford to buy for carrying, there exists at any time a demand curve for stock-carrying such as is represented by *DD* in Figure 1. Introducing the opportunity for stocks to be carried through the holding of futures contracts tends to move this

curve rightward to a position such as $D'D'$, giving an intersection at P' with the vertical, representing total stocks to be carried, at a higher level than before. Such a rightward shift clearly tends to occur if the futures market attracts many speculators who would not otherwise deal in the commodity, and it might occur also if the futures market were patronized only by dealers in the commodity.³²

The conclusion, considered in an earlier section, that hedging is done for a variety of reasons, not merely to reduce risk, carried no necessary implication that speculation should be regarded as other than pure risk-bearing; but here we have seen further evidence that futures markets are viewed much too narrowly when they are regarded as serving merely to allow transfer of risk from hedgers to speculators: The risk-premium concept has appeared inadequate, by itself, to account for observed differences in seasonal trends of futures prices. Direct consideration of returns to speculators has produced evidence that seems to require regarding the returns as mainly a wage, often negative, that varies greatly according to ability and knowledge of the speculator. And information that has become available concerning futures markets in which much of the hedging is selective, and much of the "speculation" comes from persons who deal in the commodity otherwise, suggests that they serve in large part as means by which dealers take risks discriminatingly, and make their price judgments bear more effectively on price formation.

VII. *The Place of Empirical Research in Economics*

Around 1920 and subsequently, when economics was turning strongly toward doing more empirical research, it was common for

³² The effect in the case of a futures market used only by dealers is not necessarily to move the curve to the right because DD , representing amounts of stock that dealers are willing to hold unhedged in the absence of opportunity for hedging, cannot be taken to represent also the amounts that they would be willing to hold unhedged, at the same prices, in the presence of opportunity for hedging. The possibility that such a rightward shift might occur even in the case of a futures market used only by dealers was suggested to me by the great apparent effect of the onion futures market in supporting the post-harvest price level for that commodity, which seemed difficult to explain solely on the ground of price support given by pure speculators (persons not connected with the industry) in view of the fact that, according to the available information, such speculators accounted for only about half of the long "speculative" holdings of onion futures at the times when such support was principally needed [47, p. 7].

There is a general tendency for performance of the storage function for any seasonally produced commodity to concentrate largely at some one stage of the marketing process. The concentration is most commonly at terminal markets, but it may be at country points, as for onions, or in the hands of processors of the commodity, as appears to be the case with rubber; but in any case, such concentration tends to restrict opportunity for exerting price influence through the holding of physical stocks mainly to those handlers of the commodity who operate at that stage. Existence of a futures market, allowing the many other handlers of the commodity to readily "carry" stocks by holding futures contracts against hedged stocks, would tend therefore to produce such a rightward shift as is illustrated in Figure 1, even though only handlers of the commodity used the futures market.

economic theorists to say that the function of empirical research was to verify theory. One may still sometimes hear that opinion expressed. It is an opinion that has its foundations in the philosophy of science that was elaborated by John Stuart Mill [23, esp. Bk. 3, Ch. 11; Bk. 6, Ch. 9] or else in reasoning similar to that of Mill. The feature of Mill's philosophy that gave grounds for that view had been widely recognized as fallacious before the end of the nineteenth century, and Marshall, in his *Principles*, recorded dissent from the view that economics is peculiarly a deductive science [21, p. 29]. Economic theorists have in fact rarely shown a strong feeling of need for empirical verification of theory. More typical of their attitude, at least prior to recent years, has been the aphorism, "If statistics conflict with theory, so much the worse for the statistics."

Empirical research has long been recognized as serving to clothe theory in a body of realistic circumstance that is necessary, or at least advantageous, for the practical application of theory to specific economic problems. But that use of empirical research is concerned with applied economics, not with advancing economics as a science. Though Marshall rejected Mill's classification of the sciences according to method, which had permitted regarding economics as peculiarly a deductive science with correspondingly limited opportunity for effective use of empirical research, Marshall accepted the nineteenth century view that the accomplishments of a science are to be measured by the laws of nature that it has discovered (see below); and he failed to discriminate between practical art and science. Predicting the tides "at London Bridge or at Gloucester," to which Marshall likened the tasks of economics [21, p. 32], is not an undertaking that advances science.

A third view, which has had much influence in guiding empirical research on the part of economists aiming to advance economics as a science, stems from the opinion that the chief shortcoming of economics has been a failure to quantify its laws. One of the grounds for that view has been the recognized value in natural science of quantitative investigation. The research that we have been considering here offers many examples of the values of quantitative work in economics also. But the argument for quantifying economic theory depends more particularly on acceptance of the view, prevalent in natural science as well as in economics until about the beginning of the twentieth century, that the substance of science is the body of "laws of nature" that it has discovered. Marshall's statement that, "A science progresses by increasing the number and exactness of its laws . . ." [21, p. 30] is a representative expression of the view. The turn of thinking in the natural sciences toward the conception of science that Conant has expressed particularly well may have been started by observation that the Darwinian concept of evolution continued to stand and to

mark a great advance in biological science even though Darwin's "laws" of evolution became in considerable part discredited. In physical science, the results of the Michelson-Morley experiment (1887) posed an evidently severe conceptual problem, and those results were followed by a series of other discoveries that focused attention similarly on the role of concepts in science [18, Ch. 8].

Quantifying economic theory can produce clear advantages for applications of theory to practical economic and business problems, but it is not so clear that quantifying received theory leads often to advancing understanding of economic phenomena. In the research considered here, the main useful results of attempts to quantify received theory have come through demonstration that the theory was fallacious—fallacious because of having started from wrong assumptions. The extreme example of such demonstration arose from an attempt to quantify the theory that price relations between old-crop and new-crop futures depended on expectations regarding the size of the new crop, which proved wholly untrue. After the price-of-storage concept had provided the basis for a new theory, quantification of the price-of-storage function involved in it produced some significant new information in the initial case, most fully revealed in [41, p. 556], where changes in the function from period to period are shown. Thereafter, though numerous additional quantifications of the function in specific instances could be useful for purposes of practical application, additional quantifications seemed not to offer promise of yielding further advances in understanding.³³

Economics has been forced to go through a difficult process of learning how to make effective use of observation as a continuing means of advance, after having become accustomed to rely principally on deduction from a body of observational information that remained comparatively static because it was limited largely to what could be learned from "common observation" and from introspection. The difficulty of the learning process has been enhanced by a tradition in economics of accepting problems of evident practical importance as the ones at which research should be directed. Economists have been slow to recognize the error in Mill's attempt to explain the relatively primitive state of economics as a science on the ground that, "In every department of human affairs, practice long precedes Science: systematic inquiry into the modes of action of the powers of nature, is the tardy product of a long course of efforts to use those powers for practical ends" [24, p. 1].

Natural science did not develop out of practice. That route led to

³³ The further quantifications provided in [2] and [29] may nevertheless be regarded as useful for corroboration of the original findings.

the empirical accomplishments of Watt, Burbank, and Edison, not to the accomplishments of Newton, Darwin, Mendel, or Heisenberg. Science has advanced by attacking manageable problems of acquiring understanding of observed phenomena with little or no immediate regard to evident practical importance of the problems. Seeking support for their efforts, scientists have often laid stress on the practical usefulness of scientific advance. Not infrequently they have chosen to push a particular line of inquiry because of hope that it would serve such a practical end as unlocking the mystery of cancer. But the route of science toward such an end is always that of acquiring information that promises to yield greater understanding. For example, the research economist with a scientific viewpoint who may be considering the study of futures markets does not ask himself whether futures markets are economically important institutions, concerning which conclusions are needed for practical purposes; he asks instead whether study of futures markets offers favorable opportunity for gaining understanding of the behavior of businessmen, including speculators, and of the behavior of prices of the class that we have called anticipatory. He makes his decision on principles like those that govern the decision of a geneticist considering the study of fruit flies.

The place of empirical inquiry in economic science, it appears to me, is that of making observations, statistical or otherwise, and conducting analysis such that one may be able to say, paraphrasing Conant, that in economics new concepts arise from observation and analysis, and the new concepts in turn lead to further observation and analysis.

SEASONAL UNEMPLOYMENT AND UNEMPLOYMENT INSURANCE

By JAMES O'CONNOR*

When in the late 1930's individual states wrote unemployment compensation programs into law, there was widespread sentiment against including seasonally unemployed workers under coverage. Implicit in those laws which in fact barred seasonal employees¹ was the notion that workers deliberately chose seasonal employments and therefore, during slack seasons, were voluntarily unemployed.

These provisions were not enforced; there seemed to be no way to formally distinguish between seasonal unemployment and cyclical or "structural" unemployment. What is more, it was apparent that there were no adequate operational definitions of seasonal firms or seasonal industries.

In current practice, unemployed workers otherwise eligible for benefits are offered off-season, temporary jobs. In this way "voluntary" seasonally unemployed workers are distinguished from "involuntaries"; workers who refuse off-season employments comparable to their on-season jobs are declared ineligible for benefits.² For this approach to be successful, however, comparable off-season employments must actually be available. Moreover, enforcement procedures must be efficient. There appears therefore to be some room for error in the determination of unemployment insurance claims. Probably one-third of all beneficiaries during prosperity periods are seasonal workers.³

*The author is instructor in economics at Barnard College. I am indebted to Gary Becker for helpful comments and suggestions.

¹As late as 1949, 21 states still had provisions restricting the eligibility of seasonal workers [1, p. 191].

²Agricultural workers, however, are generally automatically declared ineligible. Moreover, a certain period of work experience, or a certain income, or a combination of the two, is required of all workers.

³This estimate is derived as follows: During the prosperity years, 1955-57, of 2,936,000 jobless workers, 587,000, or 20 per cent, were seasonally unemployed [13, pp. 7, 15]. New workers, re-entries, and voluntary job changers made up 30 per cent of the total; structural unemployment, 10 per cent; 40 per cent was "not measured" by the BLS.

Of all jobless workers, 8 per cent had been unemployed for more than 26 weeks and therefore can be assumed to have exhausted their benefits. Supposing that all of the "not measured" category reflects structural unemployment, then it can be assumed that 42 per cent of all unemployed workers were collecting benefits as structurally unemployed. Next,

Conceptually, though, the notion of seasonal unemployment is clear enough. In this article, seasonal unemployment is defined as annually or semi-annually recurring unemployment *fully anticipated* by employers and employees on the basis of experience in previous years. A seasonal worker is an individual who expects each year to receive a certain amount of real income in the form of leisure.⁴ Unfortunately, as indicated above, this concept in common with many others in economics lacks a close empirical counterpart.

What is more, this definition of seasonal unemployment implies that variations in the seasonal demand and supply of labor in any given employment are stable from one year to the next. For example, if an individual found six months' employment in the garment trades last year, it is assumed that equivalent employment will be available in that industry to him this year. Actually some industries have exhibited slowly shifting patterns of seasonal variation in employment [5, pp. 144-54] [6, pp. 337-41].

Despite these problems, an attempt is made in this article to examine unemployment insurance programs from the standpoint of their effect on the allocation of labor between industries of varying degrees of seasonal instability.

I. *Unemployment Compensation and Labor Market Equilibrium*

In competitive markets characterized by *predictable* seasonal fluctuations in labor demand, equilibrium wage rates in unstable employments must be such, other things being equal, as to yield the same annual income as in stable employments. If the average utility of leisure were zero, for example, wage rates in Industry A, providing, say, six months of employment each year, would have to be twice those in Industry B, operating year-round. However, if the utility of leisure is positive, wage differentials between stable and unstable industries will be smaller. What is more, if there are seasonal fluctuations in the supply of labor (if some individuals choose to work longer than others at a given wage rate), equilibrium wage rates in unstable employments will not necessarily exceed those in stable employments. Some workers, that is, may be willing to pay a premium for an unstable employment

assume that individuals in the "new worker, etc." category were ineligible for benefits. Thus the proportion of seasonally unemployed beneficiaries to all beneficiaries was 32.3 per cent [(42 plus .20) divided by .20]. However, the fact that some re-entries may have been seasonal workers biases this estimate downward. On the other hand, the fact that agricultural workers are not eligible for benefits, yet are included in the "seasonally unemployed" figure, introduces an upward bias.

⁴ Clearly, leisure is a large component of everyone's real income. In the above context, the term refers to all leisure beyond that "earned" by the full-time worker employed year-round.

opportunity. All a priori statements about the wage structure under conditions of anticipated employment instability are therefore suspect [4, pp. 128-32] [2].

When unemployment compensation payments are newly available, the real costs of work in unstable relative to stable employments are altered. Accordingly, the introduction of an unemployment insurance program, or an increase in the unemployment-benefit/wage-rate ratio may disturb equilibrium in the labor market, producing a new allocation of resources. Unstable, eligible employments become more attractive relative to stable, or unstable ineligible employments.

This can be illustrated by a simple example: Given a homogeneous labor force, suppose equilibrium wages in employments A, B, and C are \$300, \$360, and \$840 monthly, respectively. Employment in A is stable; in B, workers anticipate three-months, and in C, nine-months unemployment annually. Assuming that there are no seasonal fluctuations in the supply of labor, the average utility of leisure is therefore \$120 monthly. All workers are indifferent on the margin with regard employment in A, B, or C, since annual real incomes are equal (\$3600) in all three.

Suppose now that an unemployment compensation plan is introduced. It is assumed that individuals in A qualify for benefits on the basis of previous income earned, yet since they are never unemployed, they are ineligible for benefits. Suppose secondly that the law specifically excludes anyone employed less than four months each year; accordingly, individuals in C do not qualify for benefits. Lastly, suppose that workers in B are eligible for payments totaling \$300 (\$100 monthly).

Since workers were indifferent with regard to the three employments before the program was introduced, and since money income in B is now greater than before, it is likely that some individuals will be attracted from A and C to B. Interemployment labor-supply shifts will produce a new equilibrium as wages are driven down in B and pushed up in A and C. In equilibrium, annual money income in A will equal money income plus leisure income plus unemployment benefits in B; both, in turn, will equal money income and leisure income in C. While it is impossible to specify the new wage structure without independent information on demand conditions, it is possible to predict the *direction* of movements in the wage rates in all three industries. Moreover, one can predict that employment will rise in B and fall in A and C.

Assume now that there are seasonal fluctuations in the supply as well as in the demand for labor. Then it is entirely possible for equilibrium wage rates in seasonal employments to be less than in non-

seasonal opportunities. Yet given any equilibrium wage structure, if individuals in B now expect to receive unemployment benefits, while those in A and C do not, the real costs of work in the three employments are altered on the margin. It will still pay some workers in A and C to shift to B. Thus in general the effects of the program on the structure of wages and employment will be similar to those in the preceding simplified model. While the new wage structure will depend on demand conditions, together with the supply of seasonal and nonseasonal employments relative to the demand for them, wages in employments where individuals can expect a large benefit income will tend to fall (or, in the context of rising productivity, real incomes, and product demands, they will tend to rise more slowly than in other industries), and wages in employments where individuals can expect a negligible amount or no benefits will rise.⁵

II. *An Illustrative Unemployment Compensation Law*

Under the laws of all states, unemployment benefit income is the product of the benefit rate and the benefit period. In a handful of states, the benefit period is constant (that is, all eligible workers receive benefits for the same period of time, regardless of previous income or work experience), while the benefit rate varies with previous income to some maximum. In most states, both the benefit period and rate vary to some maximum with income [6, App. Tables 34, 35].

In Maine the benefit period is constant. An individual earning \$100 monthly and employed for only 2 months each year is not eligible for any benefits. A worker earning the same wage and employed from 3 to 6 months or more is eligible for benefits. The benefit rate varies directly with income (or months worked) while the benefit period is invariable at 23 weeks [9, p. 104]. For example, a worker employed 5 months at \$100 a month can expect to receive \$10 weekly for 23 weeks; unemployment benefits raise his total money income by nearly 50 per cent.

Consider a worker employed for 9 months. In this case, the benefit rate is higher, \$14, yet aggregate benefits are lower (\$182 compared with \$230) since the potential benefit period has declined. The greater the period of employment, the smaller the potential benefit period, and the smaller will be aggregate benefits.

Note that potential aggregate benefits necessarily reach a maximum. For a worker earning \$100 monthly in Maine, a maximum benefit income of \$253 is associated with 6-months employment annually. Moreover, in Maine the employment period which yields the maximum benefit income is invariant, regardless of the wage rate. For a worker

⁵ In a nonstatic world, the availability of benefits will also alter on the margin the decisions of new entrants into the labor force.

earning \$300 monthly, for example, the maximum benefit income (\$506) is still associated with 6-months employment. This relationship does not hold in every other state; actually, there are three possibilities—the employment period which yields the maximum benefit income may be constant (as in Maine), or may vary directly, or inversely with the wage rate. In South Carolina, for example, the employment period varies inversely with the wage rate [11, p. 25].

Nor is it true that the maximum benefit income at a *given* wage rate will be associated with the same amount of employment (income) in one state as in another. For example, when the wage rate is \$200 monthly in Maine, maximum benefits are associated with 6-months effort, as has been shown; in Alabama, with 7-months of employment [7, p. 39].

Continuing for illustrative purposes with the Maine law, it is clear that, following the adoption of the compensation program, industries (or firms) where the likelihood of being employed 6 months (but no longer) is greatest became more attractive to workers relative to other industries. Nonseasonal employments became relatively less attractive, as did highly seasonal employments (where aggregate benefits were small or zero). Note that “highly seasonal,” “nonseasonal” and “moderately seasonal” employments are defined in terms of a given unemployment compensation law. For example, “moderately seasonal” employments refer to industries or firms where the seasonal variation is such that unemployed workers can expect to receive approximately the maximum potential benefit allowed them under the law.

In the empirical section to follow, it is not possible to make such careful distinctions. Nor is it possible to reduce the problem to the level of the firm; data are too scarce.

One further complication ought to be mentioned: If it is possible to dovetail employments, two jobs in two industries, each in production for three months, will be just as attractive as employment in a third industry, operating six months, under the Maine law. Thus, two highly seasonal employments are as attractive as one moderately seasonal job. The analysis to follow necessarily ignores this problem. Available studies indicate, though, that seasonal dovetailing is not very significant.

III. *Unemployment Compensation and the Allocation of Resources*

Ignoring for the moment the effects of the payroll taxes which finance compensation programs, benefits interpreted as subsidies clearly tend to depress wages in moderately seasonal industries, and raise wages in very unstable and highly stable industries. Labor supply shifts will bring about this pattern of wage adjustment. Marginal costs

in the former industries will fall; in the latter industries costs will rise. Under conditions of competition, these cost changes will be reflected in price and output changes. As a result, compensation programs tend to subsidize the consumers of products of moderately seasonal industries at the expense of consumers of the products of highly seasonal and nonseasonal industries.

Suppose, however, that each industry and firm bears its full share of the burden of financing unemployment compensation. Assume, that is, that the payroll tax rate is such that the total tax yield in each employment equals the total amount of benefits paid out to workers in that employment who are seasonally unemployed. The effects on the allocation of resources will then hinge on whether the tax is shifted forward or backward.

If the tax is shifted completely back to labor, it is clear that unemployment benefits cannot be interpreted as subsidies. Benefit gains are wholly offset by lower net wage rates; there are thus no incentives for interindustry supply shifts. Of course, wage rates will fall for *all* workers employed in the industry, whereas only those workers actually laid-off receive any benefits. In this event, workers who are not laid-off, and those who are unemployed for brief durations, are subsidizing those workers who are laid off and those receiving larger benefits from longer seasonal unemployment.

The problem becomes more complex if the tax is shifted forward to consumers. If industry product demand were perfectly inelastic, labor demand would not fall after the rise in product price. Hence the familiar interindustry supply shifts would occur, altering the structure of wages and employment in the direction indicated earlier. If in the moderately seasonal industries the increase in cost due to the tax is precisely offset by the decrease in cost due to the increase in labor supply, then there would be no change in the price structure. In this event, unemployment benefits would not be subsidies. This would be highly unlikely, however; for it to be true, one would have to assume a very special set of labor demand conditions. What is clear is that the price of the product of a moderately seasonal industry would rise by less than the amount of the tax because of the decrease in labor cost. But this is all that can be said with any certainty.

If product demand is not perfectly inelastic, then incentives for interindustry supply shifts will be reduced since the (derived) demand for labor in moderately seasonal industries will fall.

In the real world, for a variety of economic and political reasons, the tax burden is not borne by industries and firms in proportion to their responsibility for creating seasonal unemployment. Hence it seems legitimate to interpret benefits as subsidies; yet unless product

and labor demand conditions are specified, it is impossible to predict the effect of the subsidy on the allocation of resources, that is, on consumer welfare. Just who subsidizes whom, by how much, it seems impossible to say. While their final impact on consumer welfare may be in doubt, interindustry labor supply shifts are nevertheless likely to accompany the adoption of an unemployment compensation program or an increase in the ratio of average benefits to average wages.

IV. *Tests of the Theory*

In this section we test the hypothesis that labor supply rose in moderately seasonal industries and diminished in nonseasonal and highly seasonal industries as a result of the unemployment compensation plans introduced throughout the United States in the late 1930's.

First, how significant are unemployment benefit rates relative to wages? How important is benefit income relative to market income? Average weekly unemployment compensation payments as a proportion of average weekly earnings of production workers in manufacturing ranges from 30 to 40 per cent; the figure for New York, for example, in June 1960 was 39 per cent [10, Table A-1] [16, Table 7, p. 82]. Average weekly wages were \$89.38; average weekly benefits were \$35.12. In California, the amounts were (in April, 1960) \$102.05 and \$39.32, respectively; in a poorer state, Alabama, \$76.03 and \$22.95 [12, Table C-8, p. 37] [16]. It is clear that compensation payments are substantial both in absolute amounts and relative to earnings.

How important is benefit *income* as a proportion of earned income? In New York, estimates have been made of the average benefit period in the apparel industry, a seasonal employment, during a period of relatively full employment. In 1955-56, for workers who earned between \$300 and \$499 annually, the average benefit period was 14.2 weeks. For those who earned \$3000 or more, it was 9.1 weeks. Average weekly benefits received by the first group were \$13.17; by the second group, \$32.32. Average benefit income, therefore, for the first group was \$187.01; for the second, \$294.11. Benefit income as a proportion of earned income for the lower paid and/or short-period employment group was roughly 50 per cent; for the higher paid, longer-working group, less than 10 per cent. Clearly, employment in the more unstable sectors of the apparel industry has its attractions, especially for those who place a high value on leisure relative to income (admitting seasonal fluctuations in the supply of labor into the analysis).

Did moderately seasonal industries become more attractive, and highly seasonal and nonseasonal industries less attractive to workers, following the introduction of unemployment compensation in the late

1930's? Were there actually interindustry shifts in labor supply? If so, were there noticeable effects on the structure of wages and employment? Because data are scarce for the period, only tentative answers to these questions can be reached.

Sixteen industries for which data are available were ranked with respect to seasonal variations in the demand for labor. The latter were measured by seasonal variations in lay-off rates. This is an imperfect, but seemingly adequate measure; a fall in demand, for instance, supply constant, is likely to be reflected in a rise in the lay-off rate (of course, hours worked may fall also). Thus indexes of seasonal variations in lay-off rates have been computed; we employed the average deviation as a measure of seasonal variations in the demand for labor.

Quit-rate data, but not wage and employment figures, are available for the industries for which lay-off data can be found. It is assumed that quit-rates reflect variations in labor supply. Thus we compared average quit-rates in moderately seasonal and nonseasonal industries (as determined by the average deviation of seasonal variations in lay-off rates) for each year, 1932-41. In 1937 and 1938 (when the compensation programs were introduced) the average quit-rate in nonseasonal industries was significantly (5 per cent level) higher than in seasonal industries. For no other years were the average quit-rates in the two classes significantly different [15, July, 1937, pp. 166-75, 156-57; May, 1942, p. 1197].

Next, seasonality (or seasonal instability) was inversely correlated (Kendall rank) with quit-rates for each year, 1932-41. The highest correlation when all 16 industries were included was for 1937 ($r = .267$). On the assumption that skilled workers have more specific investment in them compared with nonskilled workers, and hence are less mobile, we next excluded from the correlations two industries employing a relatively high proportion of skilled workers.⁶ The two highest correlations were for 1937 ($r = .384$, significant at 5 per cent level) and 1938 ($r = .318$). Clearly our results are consistent with our main hypothesis.

A more direct attack on the problem was made by employing indexes of seasonal variation in employment, relating them to changes in wage rates before, during, and after the introduction of the compensation programs. For our purposes, the seasonal indexes of employment (computed by Woytinsky [5]) have one main drawback; variations in employment reflect labor supply as well as labor demand changes. However, when the rankings obtained from Woytinsky's indexes are

⁶ A multiple correlation with seasonality and skilled workers as a proportion of all workers as independent variables was attempted. However, there was too much multicollinearity for the partials to have any meaning.

compared with those obtained from our lay-off indexes, a close correspondence results (as indicated above, this comparison can be made for only a handful of industries). This drawback, therefore, is probably not very serious.

Average hourly earnings were used as a measure of wage rates. Yet as Daniel Creamer has rightly pointed out [3, p. 4], the former are by no means the same thing as the latter. An increase in the amount of overtime work, for example, will raise average earnings, but not "the" average wage rate. However, there appears to be a close enough relationship between the two to warrant using the former as a measure of the latter.

The average percentage change in average hourly earnings in non-seasonal and highly seasonal industries was compared with that in moderately seasonal industries, for a series of two-year periods, 1933-1947.⁷ Highly seasonal industries were grouped with nonseasonal industries since our hypothesis is that both sets of industries became less attractive following the introduction of the compensation programs; thus wages should have risen more (or fallen less) in both groups relative to moderately seasonal industries. It was found that average hourly earnings rose significantly more (almost at 1 per cent level) in highly seasonal and nonseasonal industries relative to moderately seasonal industries *only* over the period, 1939-1941.

Next seasonality was inversely correlated with percentage changes in average hourly earnings for a series of two-year periods, 1933-47. Four industries employing a large proportion of skilled workers were excluded, as were the three highly seasonal industries. The only significant correlations were for 1937-39 ($r = .491$, significant at 5 per cent level) and 1939-41 ($r = .299$, significant at 1 per cent level).⁸ These results indicate that there was a tendency, directly after the insurance plans were adopted, for wages to rise more slowly in moderately seasonal industries. This pattern of wage adjustment was unique to this period; it is quite possible, therefore, that it was related to the newly introduced legislation.

Turning to the effect of the programs on employment, our findings

⁷ Earnings data were obtained from [12, Table C-1, pp. 54-83]. The dividing lines between the three groups (a total of 29 industries) are naturally somewhat arbitrary. The average deviations of the seasonals of three of Woytinsky's industries were extremely large; these we classified as highly seasonal. It is less easy to justify the line we drew between moderately seasonal and nonseasonal industries. However, experimentation with different classifications did not produce significant changes in our results.

For each group, the average was computed as follows:

$$(\Sigma \text{Average hourly earnings}_{t+1} - \Sigma AHE_t) / \Sigma AHE_t.$$

⁸ For 1939-41, N was larger; thus the smaller coefficient is significant at a higher level.

were negative. It does not appear that employment rose significantly more (or fell less) in moderately seasonal industries relative to highly seasonal and nonseasonal industries during the period 1937-41.⁹ Can these findings be rationalized? Seasonal industries—during on-season periods—generally work at much greater than full-capacity to avoid the expense of idle capacity during off-season months. Thus the demand for labor of seasonal firms may very well have been quite inelastic, even during years of substantial unemployment. Thus supply changes could be expected to be reflected in wage changes, but not in variations in employment.¹⁰ Another explanation may be that the data are simply not sensitive enough to record the shifts in the labor supply.

A study of the experience in one individual state seems to bear out the latter explanation. In Delaware, workers seem to have responded to increases in unemployment benefits along the lines predicted by the theory. Delaware is one of the few states where changes in the maximum benefit rate have not been small, nor made at one- or two-year intervals. Changes in the Delaware law have been made every five or six years, when the increase in the benefit structure has been substantial [8]. In 1955, for example, the maximum benefit was raised by 40 per cent; for 1955-56, the rank correlation coefficient of seasonality on percentage changes in employment was .450. Apart from the period 1938-39 (directly following the introduction of Delaware's compensation plan), when the correlation coefficient was .60, this was the highest coefficient recorded for any two-year period, 1937-1957. There were no other significant correlations, nor were there, excepting 1949 when the maximum benefit was raised by over 30 per cent, any large changes in the law. Employment in seasonal industries in Delaware appears to be greater than it would have been in the absence of unemployment compensation legislation.

V. Conclusion

The data on the whole seem to support the conclusion that the compensation programs had a once-and-for-all effect on the allocation of labor following their introduction in the late 1930's. However, the reallocation effect implicit in the programs has probably not been of large proportions; as all students of the labor market are aware, monetary incentives must vie with many other kinds of inducements when it is a question of choosing the kind and place of work. It is highly

⁹ Since for the country as a whole the average-benefit/average-wage ratio does not rise significantly after the original impact of the state plans, more recent years have been excluded from the analysis.

¹⁰ Our findings with regard changes in average annual *earnings* are consistent with this hypothesis.

unlikely that many workers would change their jobs, and possibly their skills, for a few hundred dollars annual zero-effort income. What is more likely is that marginal workers, married women, perhaps some new entrants into the labor force, together with some part-time family workers, found seasonal employment more appealing than it would otherwise be.

Assuming that in the future unemployment-compensation plans will play a bigger anticyclical role, the average-benefit-income/average-wage-income ratio will no doubt rise. If the preceding analysis is correct, further reallocations of labor will occur. Is it possible to design a program to prevent this? One simple solution would be to reduce average benefits and at the same time make the benefit period indefinite. Thus seasonally unemployed workers would be automatically segregated from those "involuntarily" unemployed; aggregate benefits would be redistributed away from the latter to the former. Meanwhile, it would be unnecessary to enlarge the total unemployment compensation funds.

This plan would however reduce the effectiveness of unemployment compensation as an automatic stabilizer; in early stages of a recession total benefits paid out to cyclically unemployed workers would be smaller than under existing programs. Here, apparently, is one more case where policies promoting greater economic efficiency clash with those designed to reduce economic instability. Existing plans may, in fact, be the best compromise between the two.

MONEY AND CREDIT

A Review Article

By LORIE TARSHIS*

This Report¹ clearly invites review. Generously financed, written by (or for) a group of distinguished men who were "broadly representative of the various economic and social sectors of American life."² and who could call upon the services of an excellent staff and an advisory board of acknowledged experts, it was destined for best-sellerdom. It was extravagantly publicized at birth, the President accepted a copy, the Joint Economic Committee of the Congress devoted several days to it, and its back cover informs the reader that it is "the first comprehensive survey in half a century of public and private financial institutions, policies and practices in the United States." It was clearly born with a silver spoon in its mouth. But what about its foot? Does that unlikely object by any chance accompany the spoon?

A volume such as this can serve one or more of three different functions. It may, for one thing, make contributions to the science, at the very least, by bringing the newest developments in the field together, relating them to one another and considering their implications for policy—as, for example, do the survey articles in this *Review*. Secondly, it may influence policy, not so much because of what it says as because its authors carry authority with the press or Washington. Finally, the Report may be valuable as an educational tool—a document to which students can be referred for a clear and accurate account of the financial sector and its relation to other sectors—in much the way that the Report of the Radcliffe Committee is now used.

Money and Credit, to judge it in relation to these possible contributions, but in the reverse order, is unlikely to be useful to the student simply because most of its conclusions are presented with very little supporting analysis. As a political document it may be far more valuable, since the public is likely to be more responsive to the news that a particular view is endorsed by a number of well-known figures than by the information that it is supported by "the experts." Finally, as a technical document to which the professional economist may turn in the hope of finding fresh insights, the Report is quite lacking in value. It could have been written twenty years ago, though

* The author is professor of economics at Stanford University. He is indebted to J. G. Gurley and E. S. Shaw for helpful discussions.

¹ *Money and Credit: Their Influence on Jobs, Prices, and Growth*. The Report of the CED Commission on Money and Credit. Englewood Cliffs: Prentice-Hall, 1961, Pp. xiv, 285.

² Except the academic, I am compelled to note.

it would at that time have failed to secure the endorsement of a group "broadly representative of the various economic and social sectors. . . ."

The reviewer, in fairness to the authors, must bear in mind that the several possible objectives—education, persuasion, and technical contribution—like other well-known sets of goals, may not be completely consistent. Thus, inadequacy on the technical front may have been the price that had to be paid to secure the support of enough members to make the volume politically persuasive. Likewise much less analysis than would have been optimal for student use may have been thought desirable because the volume would be widely read only if it were short. The Report appears to represent a compromise, not only because it had to allow for a wide range of opinion on policy, but also because it sought various goals which were somewhat in conflict. For that reason it is scarcely appropriate to judge the Report from a narrowly technical standpoint alone; it was not written primarily for the technical reader.

Still, the economist has a right to register his disappointment, at least in general terms. For if the Report cannot be expected to carry him across old frontiers, it should be at least competent up to the borders of knowledge reached two decades earlier. And on this score I do not believe it deserves any more than a B+. Perhaps this is not surprising, but considering the inputs available (though not necessarily used) it is nevertheless discouraging.

The available inputs were generous in amount and high in quality. In addition to the members of the Commission and the Advisory Board there were 21 staff economists, and about 100 papers were especially written for the use of the Commission by outside experts.³ As a matter of fact, the reviewer, confronted by the long list of distinguished names and intriguing titles available to the Commission must present any criticism of the recommendations very tentatively; for after all maybe a Tobin or a Duesenberry has made a convincing case for them which was available to the Commission but which the reviewer will only be able to read some months hence.

Nonetheless it requires excessive modesty on the part of the profession to concede that all is well. One gains the impression that at certain points where expert knowledge was needed, it was not used. This was apparently deliberate. T. O. Yntema, a member of the Commission and in his own right one of this country's distinguished economists, wrote in a statement he submitted to the Joint Economic Committee, "We cannot leave the great problems of our economy to the experts."⁴ If this means that the responsibility in a democracy for solving them is public rather than private, it is correct, but it surely ought not to mean that recommendations for meeting problems ought to disregard the views of the experts. Yet there are too many instances in which the Committee's recommendations are sharply at odds with expert opinion, and I believe that a great opportunity has been muffed.

The staff of the Joint Economic Committee listed 77 recommendations in

³ Some of these papers are to be published.

⁴ *Hearings* before the Joint Economic Committee on Review of Report of the Commission on Money and Credit, August 14-18, 1961, 79th Cong., p. 477.

the Report and a cursory check disclosed at least 20 more. Naturally many of them can be commended, for example that urging elimination of the gold reserve requirement against Federal Reserve liabilities, or that suggesting that the President be granted limited conditional power to make temporary countercyclical adjustments in the first-bracket rate of the personal income tax. There are others having to do with the structure and organization of the Federal Reserve System which are intended to improve coordination within the system or between it and other public agencies, and these look good on the surface. But even in this area some of the recommendations have met with the strong opposition of Alan Sproul, whose opinion must be considered with special attention.

Turning our attention to matters of interest to the general economist, we have selected five areas for more detailed comment.⁵

I: *Consistency or Conflict among Goals*

First we should question the optimism of the Commission in asserting that the various objectives of economic policy—"reasonable" price stability, "low" levels of unemployment and an "adequate" rate of economic growth—to which it later adds a satisfactory international payments balance, and some others—are mutually consistent. Of course they can be made to be consistent if "adequate, reasonable, and low" are interpreted sensibly, or "if we do not expect the impossible for each" (p. 45), but this presumably means that compromise will be needed and that goals have to be tempered. If this is what is meant by "the basic compatibility of the three objectives" (p. 12), it may provide much less ground for optimism than the Commission claims; and as a guide to policy the Commission's statement of objectives may be nearly useless. Unfortunately this question of possible conflict is a real problem and its solution requires hard analysis, not verbal trickery.

Actually the Commission shows more restraint than its early statement of optimism would lead one to expect, pointing out for example that "the costs in terms of unemployment and lower growth would be so great from trying to correct our balance of payments deficit by general monetary and fiscal policies that alternative means should be sought to achieve the necessary balance" (p. 227), and that "attempts to reduce the level of unemployment below 4 per cent by stimulating aggregate demand through monetary, credit, and fiscal measures *alone* will result in an increase in the Consumer Price Index" (p. 39). This leads it to put forward a number of recommendations relating to other sectors of the economy—for improving mobility in labor markets, strengthening competition, persuading foreign governments to lower tariffs and so on. While these steps, if they can be taken, may reduce the possibility of conflict between these various goals, it is still an open

⁵ It would of course be possible to expand this treatment very considerably. How carefully, for instance, did the Commission investigate the desirability of "constant purchasing power savings-bonds"? No reasons are given for rejecting their use, so the reader must either accept the authority of the Commission, or of some unnamed expert. There is much too much of this kind of thing. The Radcliffe Committee, by comparison, in presenting arguments in favor of its recommendations prepared a far more useful report.

question whether conflict will not arise even so and compel awkward choices in the future.

This is not to say that these conflicts confront us at the present time. Our economy may still be occupying a position well inside the highest possible 5- or 6-dimensional indifference curve it is technically able to reach, and if so we could get more of every objective simultaneously. But this does not mean that choice need never be made, and the rather casual arguments the Commission presents to the contrary are not at all persuasive.

II. *The Effects of Changes in Money and Credit Markets*

The Commission could scarcely review the workings of the financial sector without looking into the effects of changes in credit conditions upon the level of activity. But on this critical issue one finds a restatement of clichés which have no more authority than that conferred upon them by their age, together with statements that deny them completely. To illustrate: the Commission at one point argues that "the sensitivity of demand for real assets to a change in interest rates . . . depends on the relative importance of interest charges and amortization payments in the total cost of the project" (p. 51). I assume that this means that the sensitivity is great for long-lived projects and is very little for short-lived ones. But on the next page we read that: "Fragmentary evidence, however, indicates that some kinds of investment are sensitive to changes in interest costs"; and elaborating, ". . . if price increases are not anticipated, investment in inventories seems likely to be somewhat sensitive to interest rates and credit terms" (p. 52). Does the term "fragmentary evidence" in this context mean unacceptable? And why should the *sensitivity* be different when prices are expected to rise? Is there any evidence for this, fragmentary or otherwise? Or reason for it? If not, is this not one of the problems of the economy that is too important *not* to be left to the expert?

Again, after salvaging some of the theoretical argument for expecting some sensitivity of investment to the interest rate (the first two paragraphs, p. 52), the Commission writes: "What little relation there might be is reduced by the tax deductibility [*sic*] of interest payments, which, at present corporate tax-rates, more than halves the after-tax effect of a given change in the interest rate" (p. 52). It then presents a counterargument which is scarcely a model of clarity or relevance, and concludes: "A change in interest rates thus does change the incentive to invest regardless of whether it is computed on a before-tax or after-tax basis."

It must be admitted that if the Report is confused at this critical point, it may merely reflect the unsatisfactory state of expert opinion on this subject. But the question still remains: how can the Commission *endorse certain policies* without having at least a consistent view as to what they will do?

III. *Bills-Only, Debt Management, and Cross-Elasticities of Demand*

Our next concern is with the once controversial questions of bills-only and debt management generally. The Commission's view which places some reliance upon debt management as a stabilizing weapon, and which urges an

end to the bills-only policy of the Federal Reserve, is implicitly based upon the belief that the cross-elasticities of demand for different kinds of government securities is low. In accord with this belief the structure of interest rates will be at least moderately sensitive to the composition of demand and of supply—whether short-term bills or long-term bonds are made available, and likewise which securities are most in demand. It is, incidentally, difficult to see any justification for a bills-only policy since if the cross-elasticities of demand are high, it makes no difference which securities are bought and sold by the Federal Reserve, and if they are low the policy makes sense only when it is desired to move short-term but not long-term yields. Thus it is easy to sympathize with the Commission's urging that that policy be dropped.

However, there is some danger that the Commission has been overly sanguine about the probable effects; and this may be misleading. The Commission is persuaded that the authorities by dealing in all maturities, whether in managing the debt or in open-market dealings of the central bank, can bring about significant modifications of the rate structure. And this would constitute a real advantage, according to the Report, since it would permit us to encourage growth, which requires low long-term interest rates, while preventing a movement of short-term capital to other countries, which requires high short-term rates.

This view, however, seems to be unduly optimistic, if it is thought that a significant modification can be obtained through operations of the customary magnitude. Of course, if the Federal Reserve buys long-term securities and the Treasury issues short-term securities, there will be some shift, but unless the scale of operations is to be far higher than is now thought to be acceptable, it is likely that the effect on the rate structure will be pretty slight.

Actually the Federal Reserve dropped its insistence upon bills-only before the Commission's Report was published, and between June 1960 (when the policy was still in effect) and October 1961 (after it had been waived), the Federal Reserve sold short-term issues heavily, while buying longer-term ones. Furthermore, during the past year the debt structure has been somewhat modified, with the sharpest change consisting in a rise in the proportion of issues with maturities of less than a year. In line with the Commission's analysis we should have expected a rise in short-term, relative to long-term rates. Actually, however, while the short-term rate fell from 2.64 per cent to 2.35 per cent,⁶ the long-term rate fell by an almost infinitesimal amount—from 3.99 to 3.98 per cent.⁷ This can hardly be described as a "shift" (in the desired direction, anyway) in the rate structure, but then the results are not really surprising. After all, the Federal Reserve is only one, and not necessarily the chief, trader in government securities; the commercial banks in the same period bought more short-terms than the Federal Reserve sold. While the recommended operations can be expected to modify the rate structure from what it would have been in their absence, to imply that they can effect

⁶ The rate on 3-months bills, newly issued, in June 1960 and October 1961.

⁷ The yield on U.S. long-term bonds, maturing in 10 years or more.

a *significant* shift, of the kind needed to stimulate private investment and attract short-term capital imports simultaneously, is to present a wildly exaggerated claim.

IV. *Controls over Nonbank Financial Intermediaries*

The Commission has had "first chance" to grapple with the problems for policy posed by the rapid rise (or more accurately, by economists noticing the rapid rise) of nonbank financial institutions. In this respect, too, the treatment is less than adequate. While recognizing their rapid growth, the Commission on the basis of what it admits to be fragmentary (again!) evidence finds that there is no need to require these institutions to hold reserves in the form of deposits in the Federal Reserve Bank against their liabilities in order to make money and credit policy more effective.

But while the Commission evidently believes that all financial institutions are equal, in its eyes some are more equal than others, for at the same time it urges that all insured commercial banks be required to join the Federal Reserve System in order to "overcome the slippage in monetary control" (p. 77) which may now occur. It admits that this is not a serious danger principally because the deposits held by nonmember commercial banks amount to less than one-sixth of the total. But nonbank financial intermediaries which in 1900 provided only 35 per cent of all financial assets, by 1958 provided 55 per cent. Are we to suppose that their activities do not contribute a potentially serious obstacle between Federal Reserve policy and the goals it seeks to achieve?

The Commission, for one, believes otherwise. In a decidedly curious display of reasoning it holds that since households tend to shift from bank deposits, cash, and investments to shares in savings and loan associations during depression, there is no additional inflationary pressure to combat during expansion. But surely this conclusion rests upon the notion that household liquidity becomes frozen in these shares and will not be used when the authorities want to restrain demand.

V. *The Balance of Payments and International Liquidity Arrangements*

We have ranged in our criticisms over all the chapters that bear upon the domestic economy. We finally consider the Commission's handling of the international aspects of monetary policy, which we find inadequate, misleading, and occasionally reckless.

The Commission implicitly recognizes the fact that our payments deficit is not only a consequence of greater inflationary pressures in this country than elsewhere. The failure of receipts to match payments (for financing imports, capital exports and government loans and grants) partly reflects structural maladjustments. Apart from obvious, but probably unimportant steps like providing better market information and export credit facilities, we must rely upon structural changes, including a speeding-up in the rate of increase of productivity, if we are to continue buying, in this extended sense, on as large a scale in the future. But the usual rules that the discipline of the

balance of payments imposes would raise serious obstacles to getting the kind of adjustment required. The Commission must be commended for emphasizing this point.

But I think the Commission minimizes the difficulties that must be faced. First, it shows an entirely unjustified optimism in seeing it as "likely that there are enough specific measures other than restrictive payments controls and changes in the exchange rate structure available to the United States and to foreign countries to permit attainment of a satisfactory balance in our hard-core accounts without a sacrifice of domestic and international objectives" (p. 231). This may be so, but in the absence of any argument in support of the conclusion it reads more like wish than thought.

Its treatment of the possibility of exchange depreciation is, I believe, poor and somewhat reckless. The argument might be appropriate for a country which used the currency of another country as an international reserve; it is completely inappropriate for a reserve-currency country; and a depreciation, even if it took the form of no change in the dollar price of gold, but a reduction in gold prices in all other currencies would do great damage to the whole payments mechanism upon which the trade of the West has been based.⁸

In order to reduce destabilizing short-term capital movements to a minimum, it is necessary to create the confident belief that exchange rates will not change; and this will be a difficult lesson to teach if changes occur from time to time. Indeed, if dealers should become conditioned to expect changes, it probably would make more sense to leave the whole complex scheme of quasi-fixed exchange rates altogether, and allow rates to be completely flexible. For with rates that are only nominally fixed, strains build up which are avoided with truly fixed rates, and yet very little of the advantages that flexible rates can secure become available. Indeed even the rather benevolent attitude taken by the Commission on this matter seems to me to be dangerous. Like "man bites dog" an academic economist cannot be expected to pass up the chance to rap the knuckles of bankers and business executives for irresponsibility and recklessness.

When the Commission comes to consider the international liquidity problem one feels that, as the Vice-Chairman in one of his footnotes of objection writes: (p. 231) ". . . these sections deal with a subject that requires profound knowledge and lengthy study in cooperation with experts of foreign countries. Moreover, CMC is not and should not necessarily be equipped to handle this subject. . . ." Unfortunately, it is hard to disagree; though there is no reason to suppose that the gap in the members' understanding of these matters could not have been filled as capably as it was in regard to most other matters by the expert staff, consultants, and special studies to which they had access.

While the role of reserves and international liquidity is set out correctly

⁸ The one advantage to be gained by appreciating all other currencies against gold is that it would not encourage speculative movements out of the dollar into gold. But gold mining would be discouraged and the value of monetary gold stocks except in the United States would be reduced, and these developments in a world that relies heavily upon gold for international reserves would be bad. Finally speculation against the dollar and in favor of other currencies would be encouraged.

in a formal sense, a good deal more should have been made of the point that the likelihood of deficits induced by structural imbalance⁹ greatly increases the need for reserves. Such imbalances can only be cured slowly even in the best of circumstances. And circumstances will not be at their best if liquidity is insufficient to permit the deficit country to finance a sustained deficit while maintaining prosperity at home.

Next, attention should have been focused on the way in which reserves grow nowadays. Apart from additions to the monetary gold stock of the nonreserve-currency countries¹⁰ their reserves can only grow by the amount of the *deficit* of the reserve-currency country. The CMC's statement that it was the strong balance-of-payments position of the United States that induced foreigners to acquire dollars as an investment may be true. But if "strong" means surplus, the result would have been to reduce the supply of dollars they *could* acquire. A surplus in our balance of payments, as we measure it, will only lead to reduce reserves for other countries.

But this exposes the problem. The U.S. balance of payments must be strong if foreigners are to continue to hold dollars as a reserve currency, and indeed to be willing to expand their holdings at the required rate; at the same time it must be in deficit if they are to come into possession of these additional dollars. Put this way, it is clear that no solution is possible. There is, however, a way out if while the deficit rules our gold stocks remain high enough and, after a certain point has been reached, increase in line with our increasing dollar liabilities. Whether a policy can be designed to meet this goal is by no means certain but it does suggest that to concentrate upon the balance of payments, as is now the mood, is to disregard at least some of the essentials. And the Commission, which at least notes the desirability of fundamental reform, deserves credit for its concern with these matters.

The Commission was apparently intrigued with the possibilities of operating on the forward foreign exchange market as a device for preventing short-term capital exports from the United States when domestic conditions require lower interest rates in this country than abroad (p. 237). I am doubtful that such an action will do anything except: (1) when it can influence expectations—that is, when it can persuade speculators that the dollar is likely to appreciate on its own; or (2) in so far as we use our holdings of foreign exchange (if we have any) or arrange for credit from, say, the Swiss National Bank to cover the contract. But presumably such a credit would have been possible even if dealings had been confined to the spot market, and it would have been equally effective as an offset. In short, I doubt very much that the Commission really has a new weapon at all; more probably it has been taken in by the current *mystique*—that it is all a matter of a delicate touch and a fine sense of timing.

VI. *Concluding Remarks*

My comments to this stage have been mainly critical. In fairness I must point out that the Report covers many areas of concern very adequately. Its

⁹ When, it should be noted, the surplus countries have no reason to seek a return to equilibrium or to want the structural adjustment that the deficit countries need.

¹⁰ Not obtained by converting reserve currencies into gold.

recommendations in the field of fiscal policy are well-drawn and imaginative, and even though they may lack proper analytical backing, they are well in advance of what might have been anticipated. Its recommendations for the reorganization of the Federal Reserve System, on the whole, point to increased efficiency and a better coordination with the Treasury and other government agencies. Some useful points are made in connection with monetary policy although it comes as something of a surprise to find in a report on money and credit that the contributions in this field (and in the field of debt policy) are so slight.

But the main value of the Report lies elsewhere: it is not so much in *what it says* as in *who says it*. It is likely to have an influence—and indeed already has demonstrated that to be so—far beyond that which its own intrinsic merits could win for it. And we can be grateful that by and large its influence has been for the good. Finally, in defense of some of its recommendations, it must be conceded that in at least some matters, the profession could not have provided unanimity of opinion for the Commission. Unfortunately there is a fairly wide dispersion of expert opinion in regard to a number of issues about which the Commission was compelled to formulate its judgment. This the individual reader must take into account when he finds something to which he takes objection.

THE THEORY OF CAPITAL

A Review Article

By VERNON L. SMITH*

W. H. Auden has said that every author probably considers his past work as falling into four classes: first, there is the unmitigated rubbish which an author regrets ever having produced; then there are the good ideas which, he painfully realizes, came to little because of his own incompetence or impatience (for publication?); third, there are the works to which he has no objection except their lack of importance; and finally, there are the products for which he is honestly grateful. Auden argues that it is the third class which must inevitably form the bulk of any collection; were the latter to consist of works falling in the fourth class alone, the volume would be too depressingly slim!

The Theory of Capital [14] is a thick collection of previously unpublished papers which, in deference to Auden's last point, has the potential advantages of multiple authorship. Though it is possible that the judgments of these papers by their respective authors already form a distribution over all of Auden's classes, I suspect a remarkably large number of them will be judged by the profession to fall into the final category. In my opinion, this book contains several important papers, and represents a valuable contribution to the resurgent interest in capital theory. I cannot commend it more highly than to suggest that every economist with analytical or empirical interests in capital theory should have a copy on his bookshelf.

This book constitutes the long-awaited proceedings of a conference held by the International Economic Association on the island of Corfu, September 4-11, 1958. Thirteen papers were discussed in eleven three-hour sessions. The papers were circulated in advance (a characteristic of the real workshop conference), and generally each session began with the author or a discussant briefly summarizing the main points of the paper, and the discussant providing his impressions, critical comments or extensions of the paper. In addition to these thirteen papers, the last quarter of the volume provides a fascinating and frequently lively summary of these discussions.

There is little reason to attempt the difficult task of providing an adequate summary of each of these papers. There is a thoroughly candid five-page over-all summary of the papers by F. Lutz in the introduction to the volume.

*The author is professor of economics at Purdue University. Assistance in the preparation of this article was received under Grant No. G-16114 to Stanford University from the National Science Foundation while the author was a visiting professor of economics at Stanford University, 1961-62.

Then there are discussions of the individual papers, which generally lead off in each case with a succinct review of the paper. The interested but busy reader is advised to consult these summaries. In several cases even the thorough reader will find it useful to read these summaries before reading the corresponding papers. A striking feature of many of these papers is their close relationship with the work of other authors and with the previous and subsequent work of some of the writers who contributed to this volume. Therefore, besides summarizing my impressions and criticisms of some of the ideas expressed in these papers, I shall try where possible to provide the reader with a guide to other important recent literature which bears immediately upon the work of this volume.

It is appropriate that the introductory paper for the conference, "The Essentials of Capital Theory," should be the product of Friedrich Lutz. This paper provides a survey of neoclassical, macroeconomic and Swedish dynamic capital theories by way of establishing the conference theme. Only the productivity side of neoclassical capital theory is surveyed; that is, the works of Wicksell and his followers Åkerman, Lindahl and Hayek are treated, but the supply side of the analysis found in the writings of Böhm-Bawerk, Fisher, and their followers is omitted. This omission is of some importance, for Lutz reports that no agreement seems to have been reached as to the choice between maximizing the internal rate of return and maximizing net present value.¹

The disagreement, it seems to me, arises largely as a consequence of ignoring the supply side. As Hirshleifer [9, pp. 329-30; 346-52] has shown, there appears to be little doubt that, provided the appropriate associated Fisherian borrowing or lending decisions are made, and we rule out certain cases which combine the difficulties of nonindependent investments and imperfect capital markets, the present value rule is universally correct. The internal rate of return is not generally correct on a Fisherian analysis and can lead to quite poor decisions in special cases.

Lutz does say that he thinks Fisher's criterion is more realistic and is preferable on theoretical grounds, but I think the case can be stated more strongly. By way of illustration, Lutz gives the tree-harvesting example in which maximization of net present value leads to the Jevons condition, which is independent of the cost of inputs, while maximization of the internal rate gives a condition (average rate equals marginal rate) dependent upon the costs of inputs. In the discussion, Samuelson's critique of this is to point out that with free entry, net present value becomes zero, and imposing this condition causes the two criteria to converge with market, marginal, and average rates all equal.

¹ However, in the discussion of Lutz's paper (as reported in the introduction to the book), there seems to have been fairly good agreement among the conference participants that Fisher's net present value is the valid maximization criterion. Except for Samuelson's paper and the ensuing discussion little mention is made of Fisher in this volume. Capital theorists commonly say little of Fisher, except to state that his contributions were very great. Leontief once suggested that this state of affairs was due to Fisher's great clarity of logic and writing style—you must write obscurely to establish a following and a school of thought!

FIGURE 1

This long-run adjustment can be illustrated with the Fisherian two-period analysis, as shown in Figure 1. W_0 is present and W_1 is future wealth available for consumption; I and I' are time-preference indifference curves; and P_0P and P_0P' are respectively the short-run and long-run productive investment opportunities open to the individual, in which increasing, then decreasing, returns to investment are assumed. Given the market borrowing and lending possibilities represented by the exchange-opportunity line QR , the individual will reduce his current endowment of wealth available for consumption, P_0 , and via direct investment move to S , then borrow in the open market to replenish his current consumption until he reaches the full equilibrium at R . This is the short-run adjustment with the average internal rate (which would be given by the slope of a straight line through P_0S) exceeding the marginal and market rates. But as others enter to exploit these physical

investment opportunities, input costs rise and, in general, the market rate of interest rises. The result is a decline in the P_0P frontier, and an increase in the gradient of the exchange-opportunity line until, say, the individual ends up with direct investment activity represented by S' , and enough borrowing to provide the full equilibrium at R' . Hence, the market rate and the marginal rate converge to the average rate at a level given by the slope of $P_0R'S'Q'$.

As a reader's guide to the Hicks and Samuelson papers, it should be pointed out that they ought to be read in conjunction with the important earlier papers by Hicks [7] [8] and Samuelson [15] on the measurement of income. The Samuelson paper extends his earlier work on measuring income to a model in which the phenomenon of investment is explicitly recognized. However, it is a one-sector model and such models can be deceptive in the sense that the world of only one product, with two uses (consumption and investment), slides over some of the interesting problems of macroeconomic capital theory. For this reason it is hardly surprising that there turns out to be no ambiguity in measuring income in the sense of Haig and Marshall (i.e., "income" is society's total flow of net product or earnings including investment and consumption, as opposed to consumption only, which was Fisher's concept of income). The production possibility functions of society for consumption and investment are -45° lines. In such a world it would appear that the distinction between the Fisher and Haig-Marshall definitions of income is considerably strained. If investment and consumption goods are indistinguishable, I should think that Fisher would be entirely willing to agree that "income" increases with net product whatever the subsequent allocation between the two uses. The stock of capital is always instantly available for dinner table consumption.

As a consequence, Samuelson, after providing a superb exposition of a model of macroeconomic growth and distribution in a one-product world with exponential capital mortality and constant returns-to-scale, proceeds to drop the model when it comes to a discussion of the evaluation of "social income." He then introduces [14, p. 45] increasing marginal rates of sacrifice of investment to obtain more consumption. This surely implies at least two sectors in which investment goods are just not available for consumption, short of gradual transformation through production into consumers' goods. This irreversibility or inflexibility that follows the commitment of resources to the capital use provides the basis for the economically meaningful distinction between the Fisher and Haig-Marshall definitions of income.

But in the end, as Samuelson shows, the real difficulty in trying to compare the welfare states of societies that produce capital goods is the simple fact that the latter are not, presumably, produced for their own sake, but for the consumption goods they allow us to produce. Hence, the usual index number reasoning that we apply to a multiproduct consumer-good world fails in this dynamic context. Samuelson ends up, as the reader might expect, with a wealth-like concept of welfare and rejects *all* current-income concepts. What we do, it turns out, is to compare the Fisherian present discounted value of future consumption levels in different situations, provided now that we use

not only the same prices but also the same interest rates in making the revealed preference comparison. But we are left with the pessimistic view that, though the solution is clear in theory, it contains so much futurity that it is practically impossible for the theory to help the statistician charged with the responsibility of coming up with a meaningful measure of "social income."

Fellner's paper is devoted to an "Appraisal of the Labour-Saving and Capital-Saving Character of Innovations." The analysis "assumes that the quantity of capital is measured by some method which enables us to distinguish between changes in this quantity and changes in the productivity of capital" [14, p. 58]. I question whether this distinction has any operational meaning at the aggregate level, but the theory is quite clear and conveys a useful understanding of the issues involved. The last part of Fellner's paper and all of the Domar paper deal with data on the U.S. capital-output ratio, so I shall deal with them together.

Fellner is concerned with implementing his theoretical analysis with the 1870-1950 data now available on U.S. capital-output ratios, and drawing conclusions about the character of innovations in this period. He is properly and commendably cautious concerning such empirical implementation, reporting that he believes "the results obtained . . . are not useless" [14, p. 58-59]. I am much more skeptical, as will be explained. Domar is concerned almost exclusively with a straight report on the U.S. capital-output data, wisely leaving open the issue of explaining these data.²

My skeptical inclination concerning the usefulness of these data in capital analysis has been heightened by Paul Anderson's recent paper [1]. Anderson gives challenging arguments for explaining the trends in U.S. capital-output ratios, both at the aggregate level and in manufacturing, entirely in terms of "technical" factors. He argues that the declining trend in constant dollar aggregative ratios from 1897 to 1949, based on Goldsmith data, is due to the rise in the capital asset deflator relative to the output deflator. The reason for this relative rise is that final output is priced on a "unit" basis, while capital assets are priced on an elements-of-cost basis. Hence, if a constant amount of labor and materials goes into a capital asset, its deflated value is considered constant even though it produces twice as much output. This criticism is not necessarily devastating, for it just might be acceptable, at the aggregate level, to measure capital in terms of the value of the inputs required to produce capital, so long as we remember that this is what we are doing, and that it may not be possible to do "better." Of course, one result of this will be to confound improvements in inputs, especially labor skill and educational level, with improvements in hardware, thereby causing trouble for the kind of distinction that Fellner's theory requires.

In manufacturing, Anderson argues very convincingly that the rise in the capital-output ratio from 1880-1919 was the result of more complete reporting of capital assets in successive censuses, and that the fall after 1919 is largely explained by the bookkeeping procedure of subtracting annual depreciation, the incentive for which was created by the corporate income tax.

² But Domar indicates that he believes the trends in these data have not been spuriously produced [14, p. 105].

This tax was actually introduced in 1909 but the rates were quite low (on the order of 2 per cent) until the war years, when in 1918, for example, the effective rates reached about 40 per cent.

Several papers in this volume deal with or touch upon the problem of measuring capital, particularly those of Lutz, Hicks, Fellner, Barna, Domar and Hoffmann. I have mixed feelings on what is generally referred to as the "problem of measuring capital." For one thing, there seems little reason to single out capital, in the sense of durable goods, as producing some kind of special problem of measurement. It is generally assumed that capital is very tricky to measure, but that labor is very easy. Labor is easy to measure because we usually count people (as if they were all identical), or, in more sophisticated versions, we compute a weighted sum of people where the weights are hours worked. The analogy with capital is straightforward. We should just count machines. Who can say that machines are more different than people? On the other hand, anyone who has followed the lead of Hollis Chenery [5], and attempted to obtain a better understanding of production functions by direct studies of technology, has found that in many interesting nontrivial processes the problem of obtaining direct physical measures of capital is relatively easy. Indeed, at this level one is able to get much better parametric measures of capital heterogeneity than of labor. But such detailed studies, though they have the very great advantage that one knows more precisely what one is doing, are not practically of much direct service in helping us to answer the great national welfare and productivity questions with which economists from A. Smith to A. Pigou have been concerned. In such matters the gulf between theory and empiricism is very wide because we do not have measures of capital in general and of labor in general that we can be sure are suitable for production functions in general.³

Apropos of some of the previous criticism, especially that of Anderson, the paper by Tibor Barna,⁴ "On Measuring Capital," is among the most valuable in this volume. Barna, thoroughly dissatisfied with our empirical knowledge of capital and our heavy dependence upon aggregate data derived from book values prepared in different ways by different firms, has undertaken direct sample surveys of British industry. These surveys provide fresh data on re-

³ In this volume there arises the question of how to measure the real value of new versus old capital. This is important for some purposes but is irrelevant for production function purposes at the process level where the proper physical measure of capital, such as pipe size, does not change with either age or value. The value may fall because in due time it is sure to leak, be subject to obsolescence, or require greater upkeep, but how much is "there" to facilitate the production of output, via a production function, does not change. I think the question is also irrelevant for aggregate production functions; for macroeconomic models are fundamentally one- or two-sector homogeneous output models, and do not really involve aggregate heterogeneous stocks of capital and labor unless we try to jam national income accounting data into them. This, by the way, seems consistent with Samuelson's view ([14] p. 332) that it is not clear that one knows what he is doing when fitting a Cobb-Douglas function for the whole economy. I think macroeconomic models are immensely valuable tools for deepening our understanding of the economic process, but I am not optimistic about the prospect of implementing them with the empirical data generally available.

⁴ See also the earlier paper by Barna [3].

placement cost, asset mortality, and depreciation. The great contribution is that these data were collected with some of the specific needs of capital theory in mind and with analytical understanding of the concepts lying behind the data.

Concerning the measurement of replacement cost, Barna's objective is to obtain an evaluation of assets that will measure the contribution that capital makes to production. He then states that the obvious answer to the search for realistic valuation is market price, but that for most fixed assets there are no quotations. For purposes of measuring the contribution that capital makes to production, I disagree that market price is appropriate. Indeed, replacement theory [16, pp. 3-4, 9] tells us that a firm should hold an asset as long as the asset's contribution to net worth *exceeds* its market value. Hence, in theory, the fact that a firm has not yet disposed of an asset is *prima facie* evidence that the asset contributes more to production than is measured by market price.

This is a subtle point in capital theory that is easily missed. We are accustomed, in measuring flow variables, to assume with theoretical justification that private and social values converge instantaneously in the market since each participant is presumed to adjust his purchases and sales of commodities until their marginal private valuations no longer exceed their external market values. However, with capital assets, in respect to the timing or economic-life decision (as distinct from the breadth decision), "adjustment" cannot occur instantaneously. It can only occur by "waiting," and as long as a firm is "waiting," i.e., holding an asset, it means that the private valuation exceeds the market valuation. This, by the way, explains why quotations are frequently not available for used assets. Where transaction (moving, etc.) costs are high, or where the asset has only one fairly homogeneous use so that all firms place a similar internal valuation on it, there will be no second-hand market. Each firm will hold the asset until it is junked.

This point, important as it might be in interpreting the Barna data, in no way reflects on the validity of the data. Quite the opposite, perhaps, for Barna measures replacement cost by fire insurance valuation, which, it seems to me, might actually come closer to measuring the private worth of assets than market price. The fire insurance valuation tends to exceed market value because, so the theorist might argue, the firm buying insurance must carefully assess the internal contribution that the insured asset makes to net worth.

Using these sample data on replacement cost valuation, Barna finds a good linear relationship between value added per employee per year and assets per employee. The intercept of this line is annual employee wages (£458), and its slope is the rate of return on capital (19 per cent). He argues that a linear relation is implied by competitive price theory which asserts that there should exist a tendency toward wage equality for the same type of labor in different industries, and for equality of the rate of return on capital. An adjustment for variation in wages with capital intensity, due perhaps to the higher skills required with a higher level of capital, gives an alternative rate of return of 16 per cent. Though the appended discussion of Barna's paper exhibits differences of opinion on the theoretical interpretation of these results [14, pp. 330-

33], there is no question that the paper is an important contribution to analytical empiricism.

A noteworthy aspect of Barna's data on mortality of assets is the finding that the mortality rate is a constant independent of age (a linear survival curve) for the age period covered (assets up to 40 years old). As to depreciation, Barna finds "surprisingly" high second-hand values, with assets being maintained in very good condition until the scrap decision is made. He finds quite often that the efficiency of plant increases, rather than decreases, with life. These results are entirely consistent with those of direct studies of engineering production functions.

The Hoffman paper, "Long-Term Growth and Capital Formation in Germany," provides a great deal of previously unpublished information. The data are time series of aggregate national income and capital stock in Germany from 1851 to the 1950's. The resulting aggregate capital (capacity) coefficient is remarkably stable over this century at 4.8:1.

Part IV of the book provides three excellent contributions to macro-economic models of growth by Kaldor, Champernowne, and Solow. These are technical papers, not suitable for leisurely general reading, though all three authors have written with pedagogical clarity. These papers are really part of an extensive series of contributions to the mathematical theory of capital and growth by Tobin [19], Solow [17] [2, pp. 89-107],⁵ Swan [18], Champernowne [4], Kaldor [10], Uzawa [20], Kurz [12], and many others.

Kaldor's paper consists of a discussion of several models, beginning with a simple classical model of growth and ending with a model of income distribution and growth. In the last model, Kaldor is concerned that it be consistent with certain approximate (or "stylized") facts such as the continued observed increase in capital per worker, a steady (as opposed to a declining) rate of profit (return, interest) on capital, the relative constancy of the capital-output ratio over long periods of time,⁶ and so on.

Solow's paper provides an elegant extension of the Åkerman-Wicksell model of capital to the problem of distributive shares under stationary conditions; then under conditions of balanced ("golden age") growth with labor growth the exogenous motive force; and finally, growth with neutral technological change. Under stationary conditions, the relative shares of profits and wages in the national income depend only on the technical parameters of the production functions in the consumer goods and producer goods sectors. Under balanced growth, the relative shares depend upon the technological constants,

⁵Two of the path-breaking papers were those by Tobin [19] and Solow [17]. Solow's Stanford paper [2, pp. 89-107] distinguishes capital goods of different vintages, and technological change occurs by embodying the latest improvements in knowledge in the new capital being constructed. This extension was an outgrowth of Solow's Corfu Conference model, as reported in the discussion [14, p. 384], and removed some artificial peculiarities from the results of the earlier model. The Stanford paper and many growth papers since have employed the analytically convenient idea of radioactive decay of capital—an assumption appearing in the Samuelson and Solow papers at the Corfu Conference.

⁶The U.S. capital-output ratio is really not very constant; see e.g. Anderson [1] and the recent paper by Klein and Kosobud [11]. Klein and Kosobud find a statistically significant long-term downward trend, 1900-1953, in the capital-output ratio of $\frac{1}{3}$ of one per cent semi-annually.

the rate of population growth and the durability of machines. An increase in durability increases the fraction of net income going to profits. Furthermore, for small increases from zero in the rate of growth, the share of profits in the national income is increased. The role of the savings function in this model is sharply illuminated. If the Marx-von Neumann assumption is made that all profits are saved and all wages are consumed, the interest rate coincides with the growth rate. On the assumption of different propensities to save out of wage and profit income, it is shown that the interest rate exceeds, equals, or falls short of the growth rate as capitalists' consumption exceeds, equals, or falls short of workers' savings. Under neutral technical progress, the income shares depend on the savings ratios and the rate of technical change, and the analysis is more complicated. In the discussion of Solow's paper, Champenowne shows that the results can be extended to the case in which the production functions for consumption goods and machines are not required to be of the Cobb-Douglas form, but are of general form apart from being homogeneous of degree one.

Two papers by A. Barrère and B. Thalberg deal with microeconomic capital theory. A major point of the Barrère paper is that capital and labor are technical complements rather than substitutes at the margin, and that the problem of the entrepreneur is to choose among alternative processes with differing capital-labor combinations. But this is precisely the programming, process analysis, approach which is not inconsistent with marginal productivity. If anything, it deepens that theory by introducing distinct processes whose range of choice provides a mechanism of neoclassical substitution between capital and labor. The programming approach, however, has largely dealt with short-run decision problems and only comparatively recently has the technique been brought to bear on long-run investment decision-making.

The Thalberg paper is concerned with the Keynes-Lerner-Haavelmo problem, to wit, if marginal productivity theory determines the demand for capital as a stock, what determines the demand for capital as an investment flow? In growth models, the phenomenon of investment demand, as a flow, is derived ultimately from some forcing function such as exponential growth in labor supply, which in turn causes the parameters of the capital-stock demand function to change over time, and *pari passu* the stock of capital to have a time derivative. Keynes argued, as is well known, that investment was determined by the condition that the marginal efficiency of investment equal the interest rate. The marginal efficiency of investment as a function of investment declines below the marginal product of the existing stock because, in part, as the investment rate increases, the pressure on the capital goods industries causes their marginal production costs to rise, thereby decreasing the return on capital. Lerner [13] elaborated on this point in his perceptive way but the issue has gained little attention until quite recently. Haavelmo [6] has now devoted a considerable part of a book to the problem and it is an important issue in Kaldor's final model in the paper discussed above.⁷

⁷ Uzawa [21] has suggested an ingenious mathematical formulation of these Keynesian concepts by introducing an explicit behavior function relating prospective returns in future years to current returns, the capital-output ratio and investment per head. These future returns are then discounted to the present to obtain the demand price of newly

Thalberg provides two models explaining the time rate of investment. In the first model, the rate of investment is explained by a behavior equation for the producers of machines which states that the rate of production of new machines is a linear function of the ratio of the price of capital goods to the wage rate. In this model, a decline in the rate of interest raises the price of capital and stimulates the output of capital goods; investment is partly a supply response phenomenon and partly the result of marginal productivity considerations. In the second model, capital goods command different prices, depending upon their delivery date. The existence of a market rate of interest means that buyers are willing to pay more for a capital good which calls for a short delivery lag. Producers, on the other hand, find it more costly to build capital goods under a short delivery contract. The resulting market for capital goods determines the number of new machines that will be built, their price, and their delivery date, as functions of the rate of interest and other parameters. Thalberg then demonstrates that a reduction in the rate of interest will, on balance, increase the number of new machines constructed.

The last paper, by J. Marchal, "Categories of Capitalists in the Theory of the Distribution of the National Income," is critical of the marginal productivity theory of distribution and expresses a preference for a theory in terms of struggles between economic groups. Such a theory, however, is not developed. The emphasis is on a discussion of the categories of income recipients that would be relevant to such a theory.

In summary, I consider this collection to be a valuable addition to the recent advances in capital theory. If some of the remarks in this review have been critical, this has been with the hope of enhancing, not detracting from, its value.

Economic Forecasting When the Subject of the Forecast Is Influenced by the Forecast¹

Economists' forecasts influence business behaviour and, therefore, the values of the variables being forecast. Forecasts of national income, for example, influence private investment outlays which, in turn, help to determine the level of national income. It is sometimes suggested that economists' forecasts are "self validating," implying that a forecast will be more nearly correct if it is made public than if it is kept a dark secret. Almost at the other extreme, there is the view that publicly announced forecasts must inevitably be invalidated by the response of the business world to the forecast. On a slightly different plane, it is sometimes argued that the instability of the economy can be traced, at least in part, to faulty forecasting and would be reduced by an improvement in the quality of forecasts.

This paper will examine the validity of these three points. It will be shown that when the variable to be forecast is itself influenced by the forecast (a) the announcement of a forecast does not necessarily validate, or tend to validate, the forecast, (b) accurate forecasting may be impossible, (c) even perfectly accurate forecasting, if it were possible, may add to the instability of the economy. The model that I shall work with is of the simplest multiplier-accelerator type and, no doubt, is grossly unrealistic. But that matters little since, for the most part, I am concerned only to produce valid counter-examples to certain generalizations.

I. Are Official Forecasts Always Self-Validating?

Suppose that at the end of each period of time the Central Bank forecasts the net national income of the following period. (The income of period t is denoted by y_t , the Bank's forecast of y_t by y_t^* .) If the forecast is announced, it is adopted without question by the business community. If it is not announced, businessmen must rely on their own guesses about the future level of income; I suppose that they adopt the simple forecasting principle that next period's income will be equal to the current period's.²

Now net national income during period t is the sum of consumption spending, c_t , and net investment spending, i_t . Consumption spending, it is supposed, depends linearly on the income of the preceding period, and investment spending depends linearly on the difference between the income of the preceding period and the income forecast during that period for the current

¹ I am indebted to C. S. Soper, a colleague at the University of New South Wales, for helpful comment on an earlier draft.

² Nothing of importance in this or the following section depends on this special assumption.

period. Thus, if the Bank's forecast is announced,

$$\begin{aligned}
 (1) \quad y_t &= c_t + i_t \\
 &= \alpha + \beta y_{t-1} + \delta(y_t^* - y_{t-1}) \quad 0 < \beta < 1 \\
 &\quad \alpha, \beta > 0
 \end{aligned}$$

where β is the marginal propensity to consume and δ is a version of the accelerator. If, on the other hand, the forecast is kept secret,

$$\begin{aligned}
 (2) \quad y_t &= c_t \\
 &= \alpha + \beta y_{t-1}
 \end{aligned}$$

In the former case the forecasting error is:

$$\begin{aligned}
 (3) \quad \epsilon_t &= y_t^* - y_t \\
 &= (1 - \delta)y_t^* + (\delta - \beta)y_{t-1} - \alpha;
 \end{aligned}$$

in the latter case it is:

$$\begin{aligned}
 (4) \quad \epsilon_t' &= y_t^* - y_t \\
 &= y_t^* - \alpha - \beta y_{t-1}
 \end{aligned}$$

It is convenient to adopt the expression:

$$(5) \quad v_t = \frac{|\epsilon_t'|}{|\epsilon_t|} - 1$$

as a measure of the self-validating power of publicly announced forecasts. If v_t is positive, announced forecasts are self-validating; if v_t is negative, they are self-destructive; and if v_t is equal to zero, the announcement of the forecast will have no effect on the forecasting error (though it will, of course, affect y_t). That in the context of models (1) and (2) v_t may be of either sign is easily checked. Thus suppose that both ϵ_t and ϵ_t' are positive. Then v_t reduces to:

$$v_t = \frac{\delta}{\epsilon_t} (y_t^* - y_{t-1})$$

and announced forecasts are seen to be self-validating only if *increases* in income are forecast; if decreases are forecast, the forecasts are self-destructive.

It is a simple matter to show that in other cases (ϵ_t and ϵ_t' both negative, ϵ_t and ϵ_t' of opposite sign) v_t is subject to a similar ambiguity as to sign. That clinches proposition (a).

In the foregoing discussion attention has been focussed on specific or "point" forecasts. It is worth noting, perhaps, that if the Bank were content to forecast merely the *direction of change* of income the forecasts could not

possibly be self-destructive. Suppose, for example, that the Bank were to forecast an increase in national income. If the forecast were kept secret, (2) would hold and

$$(6) \quad y_t > y_{t-1} \text{ if and only if } y_{t-1} < \frac{\alpha}{1 - \beta}$$

If, however, the forecast were made public, some investment spending would take place and

$$(7) \quad y_t > y_{t-1} \text{ if and only if } y_{t-1} < \frac{\alpha + i}{1 - \beta} \quad (i > 0)$$

The forecast could still be wrong, even if publicly announced. But its publication could not convert an increase in income into a decrease; and it might turn a decrease into an increase. In *that* (new) sense, the forecast *must* be self-validating. Similarly for a forecast decline in income: the publication of the forecast could not convert a decrease in income into an increase; but it might convert an increase into a decrease.

II. *Is a Perfectly Accurate Announced Forecast Possible?*³

If, for whatever reason, income during period $(t-1)$ stands at the "Keynesian intersection," that is, if

$$y_{t-1} = \frac{\alpha}{1 - \beta},$$

then, whether or not the forecast is announced, any forecast of no change will be perfectly accurate. In what follows we put aside this singular case.

Suppose, then, that the forecast is "right on the nose," with $y_t^* = y_t$. From (1),

$$(8) \quad (1 - \delta)y_t = (1 - \delta)y_t^* = \alpha + (\beta - \delta)y_{t-1}$$

Thus it appears that a perfectly accurate announced forecast is possible if and only if

$$(9) \quad \delta \neq 1$$

$$\frac{\alpha}{1 - \delta} + \frac{\beta - \delta}{1 - \delta} y_{t-1} \geq 0$$

In particular, accuracy is impossible if $\delta = 1$. Suppose, for example, that $\delta = 1$ and that

$$y_{t-1} = c_{t-1} > \frac{\alpha}{1 - \beta}$$

Then an announced forecast of no change in income will result in a fall in

³ This problem has been treated extensively by Grunberg and Modigliani [1].

consumption, and therefore income, to

$$y_t = \alpha + \beta y_{t-1} < y_{t-1},$$

and the forecast will prove to overstate income by

$$\epsilon_t = (1 - \beta)y_{t-1} - \alpha > 0$$

Nor will matters improve if an increase or decrease in income is forecast. In each case net investment spending will change by precisely the amount of the forecast change in income, leaving the error of forecast unchanged. The Bank is in a dilemma from which there is no escape: however cautious or however extravagant its forecast, it will always be proved overoptimistic, and always in the same degree.

If, on the other hand, income were less than the Keynesian equilibrium value, that is, if

$$y_{t-1} = c_{t-1} < \frac{\alpha}{1 - \beta},$$

the Bank would find itself in a similar dilemma: whatever its forecast, the forecast would prove to be overpessimistic, and always in the same degree.

But, as (9) makes clear, $\delta \neq 1$ is merely a *necessary* condition of accurate announced forecasting. Accuracy may remain beyond reach even when $\delta \neq 1$. If, for example,

$$\beta < \delta < 1$$

$$y_{t-1} > \frac{\alpha}{\delta - \beta}$$

the only accurate forecast would be of negative income. So much for (b).

III. *Does the Announcement of Accurate Forecasts Contribute to Stability?*⁴

Suppose that condition (9) were satisfied and that the Bank's forecasts were perfectly accurate. Then:

$$(10) \quad y_t = \frac{\alpha}{1 - \delta} + \frac{\beta - \delta}{1 - \delta} y_{t-1},$$

with stability condition

$$(11) \quad \left| \frac{\beta - \delta}{1 - \delta} \right| < 1$$

If, however, the forecast had been kept secret we should revert to (2), with stability condition

$$(12) \quad |\beta| < 1$$

⁴ Cf. Devletoglou [2, p. 154].

Thus while the announcement of accurate forecasts might stabilize an otherwise unstable economy ($\delta > \beta > 1$), or render an already stable economy "more stable" ($\delta < \beta < 1$), these are by no means the only possibilities. If, for example, $\beta < \delta < 1$, the announcement of accurate forecasts would convert an otherwise stable economy into a violently unstable one, with jagged, period-by-period oscillations of increasing amplitude.⁵

Of even greater theoretical interest is the possibility that the mere announcement of accurate forecasts might displace the economy from an ultimately stationary path to one of ultimately exponential growth. (Consider the case $\delta > 1 > \beta$.) This is heady stuff, to be imbibed with caution. I merely note the possibility.⁶

IV. *Announced Forecasts as Instruments of Control*

Attention has been focussed on the possibility and implications of perfectly accurate forecasting. But from the viewpoint of economic control this emphasis is misplaced. The Central Bank, as custodian of stability and growth, is not directly interested in accuracy at all. From its point of view, announced forecasts are merely means to ends, and the most efficacious forecasts may be wildly and deliberately inaccurate. This evidently raises ethical issues similar to those involved in the suppression of unfavorable war news or of unpromising medical diagnoses. It also poses a technical dilemma: to achieve economic objectives it may be necessary to repeatedly hoodwink the public; but the possibility of hoodwinking derives from gullibility, and even the most gullible will not be deceived indefinitely by the same confidence trick. In other words, the more vigorously the control is exercised the more ineffective it becomes.

The Revised Index of Industrial Production

A major revision of the Federal Reserve Board index of industrial production was put into effect in 1959. Important changes were: (1) addition of electric and gas utilities and fluid-milk processing to the index; (2) adjust-

⁵ One hesitates to draw welfare conclusions from an analysis as superficial as this, or even to criticize the view of others. It does seem, however, that the view expressed by Grunberg and Modigliani, that the substitution of correct for incorrect expectations will always bring about an improvement in the allocation of resources, stands in need of some qualification. (See Grunberg and Modigliani [1], p. 476.)

⁶ The converse is also possible: the announcement of accurate forecasts may displace the economy from a path of exponential growth to an ultimately stationary path. Consider the case $\beta > \delta > \frac{1}{2}(\beta + 1) > 1$.

ment to 1957 value-added weights for the index, covering the period since January 1953; and shift to a 1957 index base, while continuing the old 1947-49 base for summary groups; (3) adjustment of indexes to benchmarks indicated by the 1954 Census of Manufacturers: adoption of new annual indexes for 32 series, and annual correction factors for 3 series. Other changes of general interest include a new presentation by market groupings, and improved seasonal adjustment factors.

All of these revisions are good in principle, and some, notably the market-grouping presentation, may prove of considerable analytic value. However, there are questions concerning the way in which these changes were carried out, and as to the over-all accuracy of the revised index.

The new index, since the start of 1951, has increased more rapidly than the old. By mid-1959, when the substitution was made, the new index was 8 per cent higher than the old, representing an average spread of about 1 per cent per year. It is the contention of this paper that the new index has an upward bias, which may account for all or most of the difference from the old index, and which continues to operate at an annual rate which may be as high as 1 per cent per year.

Particular criticisms, which in most cases contribute to this general conclusion, concern:

1. Use of four separate series for electric power, with a much higher weight for the rapidly growing residential power series, instead of a single series, and the exclusion of electric power produced by industrial corporations. Use of a similar method for gas.

2. Weighting of electric power and gas to include extensive distribution activities. Weighting of important manufacturing series to include extensive and relatively increasing distribution and advertising activities, notably fluid milk, drugs, bakery products, cigarettes.

3. Excessive use of deflated-value series instead of physical production series, and the application of inadequate price deflators to them.

4. Use of exaggerated quality corrections for automobiles and possibly for other series.

These criticisms apply particularly to the annual series, which govern the trend of the index, and not necessarily to the monthly series .

I. Electric Power Index

The new electric power index was first prepared in 1956, and combined into the over-all industrial production index in the latest revision. By 1960 this electric power index reached 319.9 per cent of the 1947 level,¹ while actual electric power output, as measured in kilowatt hours, reached only 273.4 per cent of the 1947 level. Certainly this latter substantial increase should be included in the index of industrial production. What is at issue is the inclusion of the considerably faster increase shown by the FRB electric power index.

¹ Here as elsewhere, FRB index numbers are taken or computed from indexes contained in [8] and current industrial production releases of the Federal Reserve Board.

Almost half the divergence is due to the omission of direct production of electricity by industrial establishments. During the postwar period, industries have obtained a more than proportional part of their increased power needs from public utilities. Industrial establishments generated 16.8 per cent of the country's total power output in 1947, but only 10.4 per cent in 1960. Obviously, this omission significantly raises the trend of the index. The basis for this omission is the view of the Federal Reserve Board that indexes should be compiled on an industry rather than on a product basis. That is, its preference is to include all of the variety of products made by the establishments of a given industry in one index, instead of grouping all output of a given product, no matter where it is made. For example, an index of production for the steel industry, covering all its products, may have a different trend from an index of output of the product steel, no matter where made. But the over-all index of industrial production, embracing the totality of industrial commodities, should be the same whether added up according to products or according to industries.²

Referring to the industry index approach, Clayton Gehman of the Federal Reserve Board explained in a communication [3] to the author:

Power production by industrial users is not directly represented by any monthly or annual series. It is, however, indirectly represented by the series used, which generally pertain to the primary activities of the industries in question. To provide direct representation would require that the power generated be spread among all the industries which generate their own power. This would be a troublesome adjustment, although in principle perhaps a desirable one.

But actually, there is no requirement to spread the industrial power production among the producing sectors. In practice, the revised FRB index is consistently on an industry basis only in the calculation of value-added weights. It is really a mixture of industry and product series. In all sectors where direct production data are used as a measure of output change there is no adjustment in the index for fluctuations in output of items not normally made by the responsible industry, nor in output of the measured item by outside industries. Production of steel by Ford and International Harvester is not separated out and credited to the automobile and farm equipment industries respectively. The FRB does not segregate and distribute among users captive production of iron and steel castings, which account for 40 per cent of the total, or captive coal output, also very important.

It would appear more consistent with the procedure for other easily measurable commodities to include all electric power on a product basis. The overriding point is that electric power output by an industrial plant is just as much a part of over-all industrial production as electric power output by a public utility. It should be included in the total production index, no matter where it is classified, and even if it does not appear in any industry index.

The indirect representation claimed is of dubious significance. Practically,

² For a full discussion of the two methods see [15, pp. 14-17].

it refers merely to inclusion of captive electric power in the value-added weight base of an industry. This is *not* equivalent to including the trend in captive power output, except in the unlikely event that both the proportion of captive power in total power use and the consumption of power per unit of final output remain constant. Since actually the proportion of captive power in industrial use has been declining, inclusion of an assumed constant proportion by representation in the indexes of consuming industries carries forward the upward bias in the index. Anyhow, the value-added weighting mechanism is not sufficiently refined for this type of representation to be really effective. At best it is a poor substitute for direct inclusion of all power output.

The differential weighting of a kilowatt hour of utility power output is as follows (taking the weight of a kilowatt hour of power sold to industrial users as 100): residential, 225; commercial, 210; industrial, 100; Atomic Energy Commission, 30.³ Between 1947 and 1960 the heavily weighted residential power consumption increased more than four times, while lightly weighted industrial use increased only two and one-third times. The very lightly weighted use by the AEC increased 33 times during the 13-year interval, but this offset less than half the bias resulting from overweighting of residential use, owing to the small initial quantity involved. Moreover, since 1955, AEC use has risen less rapidly than total power use, so its light weighting has reinforced the upward bias deriving from the heavy residential weighting.

Combining the effects of omission of production by industrial establishments and of unequal weighting, starting with 1947, we find that the excess of the FRB index over the actual trend of power output reached 6.6 per cent in 1950, 10.1 per cent in 1953, 11.2 per cent in 1957, and 17 per cent in 1960. The varied pace of increase in the bias reflects mainly changes in the trend and importance of AEC power use.

The FRB differential electric power weights are computed from differential revenues received, assumed to be proportional to differences in value added per kilowatt hour. The purpose is to include distribution as well as production activity by utilities [10]. At the point of production, each kilowatt hour of power is equal, regardless of its destined use. But there are great differences in distribution cost as between various markets, possibly reinforced by inverse differences in bargaining power amongst these markets. Gehman makes the case for this method:

The basis for assigning more weight to a kilowatt-hour used in residence than to a kilowatt-hour used in a factory is that the former, on the average, carried more distribution and service activity with it than the latter. This is not a very convincing basis if production is thought of as purely commodity-producing activity; but it does make sense if the industrial production index is thought of as measuring the contribution to the nation's total output of goods and services made by establishments classified in the industrial sectors of the economy. The critical

³ Computed from production data of the Federal Power Commission and weights contained in [8, p. S-18].

distinction is between a measure covering certain activities and a measure covering certain establishments. [3]

Following this argument to its logical conclusion, we would have to exclude from industrial production the output of factories owned by Sears Roebuck, a distributing company, and include the retail activities of outlets directly owned by gasoline refining companies, with sharp jumps and drops in the index resulting from changes in ownership. We would include the financial activities of auto company credit subsidiaries, exclude the oil production in Southern Pacific wells, but include rail and ship transportation of steel company subsidiaries. We would end up with a hodge-podge, and not an industrial production index.

It may be argued that these examples are extreme because Gehman refers to "establishments," not financial units. However the distribution and service activities of the power companies are mainly based not on the power stations, but on the offices of the companies, which are widely separated from the power plants and in the field. The FRB is not using "establishment" in the narrow Census sense, but in a much broader sense which includes varied operations at different locations.

An index of industrial production *is* a measure of "purely commodity-producing activity," as Gehman puts it. The United Nations publication setting international standards for such indexes states this quite definitely:

It is concluded that the title "index number of industrial production" can be retained as the description of an index which combines series representing changes in the volume of work done in various sectors of industry, limited to the production of commodities, excluding agriculture and services [13, p. 7].

The present index of electric power output should be replaced by one measuring completely and uniformly the output of electricity by all producers, industrial and utility. The market-grouping indexes should be retained for purpose of analysis, but weighted in proportion to kilowatt hours in the base year. Similar considerations apply to gas.

II. *Overweighting Certain Industries*

The overweighting of residential and small commercial power, by inclusion of distribution and service charges in the weight base, also occurs in the weighting of electric power as a whole, increased by the inclusion of general advertising and distribution expenses. Thus the total electric power index, besides having an upward bias, is overweighted as a component of the total industrial production index. Since electric power production rises more swiftly than industrial production as a whole, this is an added source of upward bias.

Residential electricity and gas account for 7.26 per cent of the total weight for consumers' goods in the FRB index, as compared with 3.39 per cent of consumers' expenditures for commodities, as reported by the Commerce Department. On the other hand, fuel oil and gasoline account for only 3.82 per cent of the consumers' goods segment of the FRB index, but are 7.58 per cent of all consumers' commodity outlays.⁴

⁴ Adjusted to include residential gas and electricity in commodity outlays, instead of

The index weight of residential utilities, relative to consumer outlays, is about four times as great as that for consumers' fuel oil and gasoline. A major part of this discrepancy is due to the fact that distribution and service costs and charges, which are important in both cases, are included in the index weight base for the utilities but excluded from that for fuel oil and gasoline. In recent years output of the latter commodities has increased but slowly, in sharp contrast to the former. Thus the relatively high weight for consumer utilities, and the relatively low weight for consumer fuel, combine to give a sizeable upward bias to the index as a whole.

Similar discrepancies apply to the weighting of a number of manufacturing industries. The point can be brought out by comparing FRB value-added weights with production-worker man-hours in 1957. For manufacturing as a whole the FRB allots .3430 points of weight per 100,000 man-hours. For cigarettes the ratio is .9819, for cigars .1979.⁵ Cigarette manufacturing has been rising steadily, while cigar production has been relatively stagnant. So the overweighting of cigarettes unduly raises the trend of the tobacco products group as a whole.

In general, use of value-added weights is superior to use of man-hour weights because of differences in wage-levels, reflecting different average skills, and differences in the value of fixed capital invested per man-hour, both of which are mirrored more or less appropriately in value added. However, the five-to-one difference between cigarettes and cigars is only attributable in minor part to such normal factors. It results mainly from large-scale advertising and other nonmanufacturing items included in value added for the cigarette industry. Cigarette companies spend on advertising alone one and one-half times as much as they do on wages and salaries. And these outlays are then marked up by unusually favorable profit margins made possible by the small numbers of producers, the steady demand, and the historical success of resale price maintenance.

Similarly, the weight for fluid milk per 100,000 man-hours is .5789, of ice cream .5449, and of other dairy products (butter, cheese, condensed and dried milk) .2275. Extensive distribution activities by dairy companies account for the relatively high value-added to man-hours ratio in the first two industries. The fluid milk industry pays more in salaries to delivery-salesmen than to production workers. Here also the higher-weighted products have a steeper upward trend than the others.

The chemicals group has .6554 points of weight per 100,000 man-hours. This reflects, largely, the high wage rates, research expenditures, and capitalization of many chemical industries. But the very highest ratios are for drugs and soap, 1.0162 and 1.1219 respectively. These are low-capital industries; but they do have enormous advertising and promotional expenditures, which account for the exceptionally high value-added to man-hours ratios. The index for drugs, soap, and toiletries, with such a high relative weight, rises much more rapidly than the over-all industrial production index, and

services, where they are placed in the existing GNP classification. Consumers expenditures percentages for 1957 computed from [12, Table 15, p. 14].

⁵ These and subsequent similar calculations were made from data contained in [14, Table 1], and [8].

somewhat more rapidly than the major chemical, petroleum, and rubber products group of which it is part.

Soft drinks is another rapidly rising industry with its weight inflated by distribution activities. However, to a lesser extent the same is true for the slowly rising bakery products industry, and the comparatively stagnant beer and ale industry.

Despite these exceptions, a high weight, based on inclusion of distributive-promotional activities, is generally given to the more rapidly growing industries. This is to be expected, for rising market prospects stimulate advertising, promotion, and direct distribution activities, and the realization of these prospects provides the manufacturer with the financial means for carrying on these activities on an expanding scale.

The FRB statisticians estimated for broad groups the change in weights that would result from exclusion of advertising and other business services. They concluded that the changes would not be sufficient to justify the effort [8]. However, the corrections should be made for individual industries, and should be designed to exclude *all* distributive and service activities, notably direct retailing by manufacturers, and the mark-ups on cost of these activities, from value added as used for weighting purposes. The FRB and the UN agree on the desirability of such exclusion, the latter agency with considerable emphasis [8, p. 30] [13, p. 18]. Certainly estimates would be necessary, but their probable error would be less than the certain error now existing from failure to make the correction. The result of the correction would be a more accurate, and more slowly rising, over-all index.

III. *Excessive Use of Deflated Value Estimates*

The FRB index was originally constructed exclusively from quantity series. Later, to increase coverage, man-hour series, corrected for estimated productivity changes, were added. After the Second World War, annual adjustments were made to the latter series and to some incomplete production series by means of more accurate production data available only yearly. Being concerned with trends, we will limit attention here to the annual series. The 1953 revision, the first to apply the adjustments comprehensively, introduced the deflated value series as an annual adjustment mechanism. This is common enough in GNP analysis, but had not previously been considered suitable for construction of industrial production indexes. The use of deflated value series, and of combinations of value, quantity, and man-hours sources, has been so increased in the latest revision that industries with less than half the weight of the global index are governed by exclusively quantitative annual series. This is illustrated by Table 1.

The outstanding change is the rise in the importance of deflated value series from 9 per cent in the 1953 revision to 27-37 per cent in the 1959 revision. Moreover, in the case of durable goods, the most volatile and sensitive sector, deflated value series account for 20.26 points out of 49.66 points total, considerably in excess of the 13.52 points in quantity series, and probably accounting for over half the total group weight with proper distribution of combination sources.

The specific utility of an index of production depends upon its construction from physical quantities and not values. It is a measure of how much was produced, not how many dollars the product sold for. A price-index deflation may approximate the same result, but it is subject to a second order of error, and should be used only as a last resort. A direct quantity measurement, even one involving some estimation, is usually preferable.

TABLE 1—WEIGHTS OF SOURCES OF ANNUAL DATA: FRB INDUSTRIAL PRODUCTION INDEX 1953 AND 1959 REVISIONS

Source	Base Period Weights (per cent)		
	1953 Revision	1959 Revision	
		A	B
Physical Quantities	76	47	57
Manhours	4	3	6
Deflated Values	9	27	37
Other and Combinations	12	23	0
Total	100	100	100

1953 Revision from [9]. Physical quantities includes use of materials consumed, accounting for 12 weight points.

1959 Revision compiled from [8, pp. S-4-S-19]. In column A no attempt is made to distribute combination sources. In column B equal distribution among combination sources is assumed. E.g., 16.48 weight points are derived from quantity and value combinations. In column A, they are included under "other and combinations." In column B, 8.24 points each are attributed to physical quantity and deflated value sources.

This was clearly recognized by the FRB statisticians in compiling the 1953 revision:

. . . industry value figures, materials consumed, and man-hours—are inherently less reliable for production measurement, even after adjustments for price changes and so forth, than well compiled data on physical output, which ordinarily are not tabulated by industry of origin. In developing the production index, quantity of output figures were usually selected in preference to the other types of data despite the fact that they did not correspond exactly to the industry concept desired, unless they also suffered from other deficiencies, such as inadequate coverage [9].

This comment applied specifically to annual series. Almost half the monthly series were based on man-hours, which was considered reasonable because they were adjusted annually by the more complete and accurate physical quantity data. Similarly, the UN statisticians regard quantity and deflated value series as equally good for short-period changes, but state that for linking benchmark intervals of five years—or preferably one year—use of deflated value series is not justifiable, and weighted quantity indexes should be used [13, pp. 25, 39 ff].

As indicated by this source, weighted value indexes are particularly un-

desirable when used for long-period indexes of production, such as those which are computed from major Censuses of Manufactures and serve as benchmarks for FRB index revisions.⁶ The 1947-54 Census indexes, for the first time, used a substantial number of deflated value series. This reduces the value of these indexes as benchmarks, or as verification for the validity of the 1959 revision, as cited by the FRB [8, p. 21]. The agencies involved should refrain from repeating this practice in future benchmark calculations.

In the 1939-47 Census calculation, the statisticians handled those industries lacking quantity data by assuming productivity changes parallel to those observed in industries within the same group for which quantities were available. This would be valid, as would also the alternative method of assuming parallel changes in value added per unit of output. While the latter method involves a price index of sorts, it is one wholly derived from the observed data, and is set up merely as a computing medium [15, pp. 11-14].

While deflated value series have a wider range of error than quantity series, they have no intrinsic bias. In two cases, checked by this writer, deflated value series used by the FRB corresponded reasonably well with benchmark calculations based on physical quantity data contained in the 1947, 1954, and 1958 Censuses of Manufactures. These were soap and related products, and bakery products. However, in other very important cases, the deflated value series have significant upward biases, stemming in part from the use by the FRB of specially constructed price indexes as deflators.

In the 1953 revision the FRB statisticians almost always identified their price deflators as BLS indexes. However, they give no identifications in the 1959 revision. They have constructed or used, special, unpublished indexes for major sectors where they regard the BLS indexes as biased upwards [8, p. 72] [2, p. 40]. These specially constructed FRB deflators, rising less than the BLS indexes, deflate value figures less, and result in faster rising production indexes. This is related particularly to quality changes, for which, in the FRB view, prior indexes make inadequate allowance. The FRB used special price indexes, or made other special adjustments, to correct for quality changes for electrical generating apparatus, locomotives, telephone equipment, automobiles, and other items [8, p. 72].

We agree that the allowance for quality changes is often difficult to measure, but is an important factor. In some cases it can be calculated more or less readily. For example, one can base an index on the capacity of steam-turbine generators, rather than on their number or weight. But not all quality changes represent measurable improvements. During the postwar period of rising prices, manufacturers have often made price increases indirectly, through the introduction of new models at higher prices. Such new models may or may not include a real improvement in quality, and rarely one proportional to the rise in price. Sometimes, especially in the case of consumers' goods, there is only a packaging shift. In some cases the new model is inferior in quality.

⁶ Computed originally by Solomon Fabricant and the Nation Bureau of Economic Research, they were jointly calculated for the 1939-47 Census interval by the Census Bureau and the Federal Reserve Board, and for the 1947-54 interval by these two agencies and the Bureau of Labor Statistics.

Moreover, existing BLS indexes appear generally to give full allowance for quality improvement. The Bureau's procedure of linking price quotations for identical specifications, and splicing on new and improved specifications at the old index level, automatically deflates for quality improvement. For example, the Bureau, in compiling its consumer price index, has "linked out" of the index for one low-price make of automobile in one city a total of \$669, or, in 1960 prices, \$832, mainly on account of quality changes, over the interval 1939-1959. Three-fourths of that downward adjustment occurred since 1954 [11].

If the BLS may fail to link out some quality improvement, it may also incorrectly link out price increases introduced in the form of new specifications not involving proportional quality improvement. Nor do its indexes catch cases of reduced durability of certain commodities.

The question of appropriate allowance for quality change in index number construction is a subject of controversy, especially in respect to BLS indexes. This writer agrees with Milton Gilbert's conclusion [4, p. 997]:

It will readily be seen that the flights of fancy which would correct for the imagined upward bias in the cost-of-living index, because of lack of correction for quality change, would give doubtful results when transferred to the production index. . . .

Apparently the FRB takes a different view. Objection here is raised to its use of unpublished and undocumented price indexes, contradicting established indexes, as major ingredients in the preparation of its production index.

Also, wherever price index adjustments can be made for quality factors, corresponding quantity adjustments can be made directly. The FRB shifted from a physical volume index for machine tools to a deflated value index. The quality factors used in composing its price deflator could be applied, with appropriate formal variations, to the previously used physical output series. This would avoid the independent error introduced through an intermediate price series. Moreover, the quality factors considered should be published in sufficient detail to permit independent verification and criticism.

The extremely important market category of business equipment accounts for 12.16 base-year points in the index. It is most dependent on deflated value measures, with 9.91 weight points calculated in this way, and only 1.70 points by simple quantity measures. The FRB compared Commerce Department constant-dollar producers' goods expenditures with the FRB index for this group for the period 1953-59. It found a marked divergence after mid-1957, with the FRB index ending up relatively higher by 10 per cent [8, p. 73]. The FRB attributes the discrepancy to an excessive rise in the Commerce price deflator. This appears unlikely, since the deflator increased only 5 per cent between 1957 and 1960, half the amount of the discrepancy. The FRB explanation implies a 5 per cent *decline* in average prices of equipment, while trade reports of the period conform generally to the modest rise in the Commerce deflator.

The divergence is even more striking if carried back to 1947, but its impact is mitigated by points of noncomparability in coverage between the Commerce producers' durables group and the FRB business equipment group. A more

TABLE 2—PRODUCERS' AND GOVERNMENT PURCHASES OF DURABLE EQUIPMENT,
IN CONSTANT DOLLARS, AND FRB INDEX OF PRODUCTION OF EQUIPMENT
AND EQUIPMENT MATERIALS SELECTED YEARS, 1947-1960

Year	Durable Equipment Purchases		FRB Production Index, Equipment and Equipment Materials Combined	
	1954 Dollars Billions	Index 1947 = 100	Index 1947 = 100	Percent of Durable Equipment Purchases Index
1947	25.3	100.0	100.0	100.0
1950	26.9	106.3	103.2	97.1
1953	44.3	175.1	185.5	105.9
1957	41.6	164.4	191.4	116.4
1960	37.6	148.6	195.8	131.8

Source note: Durable equipment purchases compiled from [16, Table VII-6, p. 224] and [12, Table 66, p. 31].

reliable comparison is obtained by relating the Commerce series, in constant prices, of private and government expenditures for durable goods to the FRB index for producers' equipment, defense equipment, and producers' equipment materials, combined with appropriate weights.⁷ This comparison is shown in Table 2.

Between 1947 and 1960 the FRB series rose almost twice as much as the Commerce series. The discrepancy builds up steadily after 1950, cumulating to 31.8 per cent by 1960. If interpreted as an upward bias in the FRB index, it contributes, by 1960, an upward bias of 7.54 per cent to the entire index, or over one-half of one per cent per year.

Sufficient quantitative data are available to provide a sound basis for a genuine production index for equipment. The Commerce Department, in its *Facts for Industry* series, publishes quantity data annually or more frequently for products which, with closely dependent items such as spare parts, account for more than half the value added in the manufacture of nonelectrical machinery. Besides taking steps to broaden that coverage, the gaps can be filled by use of man-hour statistics, corrected by productivity indexes inferred from related branches for which quantitative data are available.

Value deflation of the annual drugs and medicines index also has serious consequences. The index is not published regularly, presumably because of its unreliability. But it has a significant impact, because of its 1.16 points of weight, and its rapid rise. In a special listing of consumers' goods, the FRB showed drugs near the top, with an index of 323 for the first half of 1959,

⁷ The FRB defense equipment group is incomplete. A rising proportion of defense equipment is included in the FRB business equipment group, and some in business equipment materials. Hence the combination of government and privately purchased nonconsumers' durable items for both the Commerce and FRB series gives a better comparison. More precise comparability would be obtained by adding net exports and inventory accumulation of producers' and defense equipment to the Commerce figures. The trends have been such that this would enhance the contrast shown by Table 2.

on a first-half 1947 base [8, p. 10]. Commerce Department estimates at current prices show consumer spending for drugs and medicines in 1959 at 274 per cent of the 1947 level [16, Table II-4, p. 150] [12, Table 15, p. 14]. Since foreign trade and government purchases did not change so as to affect the comparison materially, these two indexes, if both are correct suggest a 15 per cent decline in the average price of drugs between 1947 and 1959. The BLS consumer price index shows a rise of 23 per cent, its wholesale price index a fall of 10 per cent. However, in this case, none of the standard price indexes can be taken seriously, and for that reason were ignored by the FRB in its 1953 revision [9, pp. 1272-73].

The BLS overcorrects for quality improvements, fails to measure price increases concealed through varied packaging, and overweights declines of new drugs from prices when they were in the experimental stage. Its method does not take into account the standard industry practice of introducing new forms of old drugs at higher prices, to cash in on novelty value, then letting the price taper as still different forms are introduced at still higher prices.⁸

The trade publication *Drug Topics* reports annually the average price of a drug prescription. This increased from \$1.361 in 1947 to \$2.830 in 1959 and \$2.980 in 1960 [6]. Taking 1947 as 100 the index would be 207.9 for 1959 and 219 for 1960. Despite obvious weaknesses, this series is much closer to reality, as reflected in common experience, than the BLS or implicit FRB indexes. As a test of consistency, when combined with the Commerce dollar expenditure series, it suggests a fairly steady growth in the per capita quantity of drugs consumed of about $\frac{1}{2}$ per cent per year. This appears more realistic than the FRB index, which implies a per capita increase in drug consumption of $2\frac{1}{2}$ times in 12 years.

The drug and medicine series should be improved. If necessary, man-hour statistics would be preferable to those now employed, or even the device used in the 1953 revision, which used very partial quantitative data. The best solution would be to obtain from the industry annual quantity data for groups of products already covered by dollar shipments in the Annual Survey of Manufactures, with some increase in detail if possible.

The following general procedure is suggested for annual indexes to replace those now based on deflated value series:

First, use should be made of all currently available physical quantity data, even where it is not of the best, and not corrected for quality changes. Second, arrangements should be made with trade associations to obtain, at least for the purpose of compiling the industrial production index, annual figures on production now compiled for intra-industry purposes. Finally, the Census should collect more annual quantity-of-production data in the Annual Survey of Manufactures. Such an addition would place but a trifling burden on the manufacturers, especially since almost invariably it would cover items for

⁸ *Business Week* describes this process as pricing new products "as high as the traffic will bear," to get a "fast profit," before competition forces a cut in the initial price [7]. Richard Carter quotes from the *New England Journal of Medicine* to cast doubt on the quality improvement supposedly contained in new drug models [1, p. 138]. Relevant data are also contained in the Kefauver hearings on drug prices [17].

which the production statistics are compiled for internal and/or trade association use.

Lastly, when production statistics are not obtainable by any of these means, man-hour statistics should be used instead of deflated value. The productivity correction factor should be derived by using the productivity change observed in the most closely related industry for which physical output figures are available.

IV. Invalid Quality Corrections

The FRB has adjusted the numbers of passenger cars produced for changes in (a) make and model; (b) auxiliary equipment; and (c) body styles. In principle this is a valid approach to quality correction. For the entire interval 1947-

TABLE 3—ADJUSTMENT FACTORS FOR PASSENGER CAR PRODUCTION 1956-1960;
INDEX NUMBERS, 1956=100

Year	Adjustment Factor			
	Car Models	Body Style	Equipment	Combined
1956	100.00	100.00	100.00	100.00
1957	100.18	100.48	100.83	101.50
1958	98.41	100.37	100.37	99.14
1959	97.58	100.37	99.76	97.71
1960	95.60	100.25	99.11	94.99

Source: Compiled from data contained in [18] and [5]. Weight factors applied as follows.

Car models: compacts, .8; Rambler and Studebaker, .9; "Big Three," 1.0; medium-priced cars, 1.2; high-priced cars (Lincoln, Cadillac, Chrysler, Imperial), 2.0.

Body style: per cent addition for 4-doors, 2; convertibles, 10; hard tops, 4; station wagons, 6.

Equipment: per cent addition for automatic shift, 7; power steering, 3; power brakes, 2; V-8 engine, 5.

1960, the number of automobiles produced increased 88.3 per cent, but the FRB revised index increased 141.4 per cent, an upward correction of 2 per cent per year.

We have reviewed this correction in detail over the last four years. We find it excessive, and in the last three years in the wrong direction. The movement toward more expensive, more powerful, larger and more elaborately equipped cars reached its peak in 1957. Thereafter the trend has turned downwards in one indicator after another, accelerating in that direction with the introduction of the "compact" cars in the 1960 model year.

Automatic shift equipment reached a peak of application on 79.9 per cent of cars in 1957, falling to 71.4 per cent in 1960. Cars with V-8 engines fell from 82.7 per cent in 1957 to 58.6 per cent in 1960. The proportion of highest-price cars fell while that of economy cars increased sharply. Average horsepower fell 23 per cent in the last two years, and in 1960 was below the 1955 level [18, 1961].

We have computed quality adjustments for the period 1956-60, covering about the same factors as the FRB, with results shown in Table 3. It is not

claimed that these adjustments are either complete (since there is omission of some equipment) or without a degree of duplication (as between car models and equipment). But it is claimed that they are correct in direction and in order of magnitude.

Table 4 compares for the same period indexes of the number of automobiles produced, this index corrected by the factors derived in Table 3, and the revised FRB index. For 1957, FRB made an upward quality adjustment of 3.6 per cent, instead of the 1.5 per cent shown in Table 3. For each of the following three years, with significant downward quality corrections indicated by the data, the FRB continued to make substantial upward corrections. The annual bias in the FRB correction averaged about 4 per cent per year. The cumulative bias for the four years is 16.6 per cent contributing an error of

TABLE 4—INDEXES OF PASSENGER CAR PRODUCTION, AND
QUALITY CORRECTION FACTORS, 1956-1960

Year	Production Indexes, 1956=100			Annual Quality Correction Factors Per Cent		
	Number Produced	Adjusted by Table 3	FRB	Table 3	FRB	Upward Bias, FRB Correction
1956	100.0	100.0	100.0		-	
1957	105.4	107.0	109.2	1.5	3.6	2.1
1958	73.1	72.5	77.8	-2.3	2.7	5.1
1959	96.4	94.2	104.9	-1.4	2.3	3.8
1960	115.4	109.6	127.8	-2.8	1.7	4.6

.6 per cent to the index as a whole, on account of the 3.6 per cent weight of passenger cars and original equipment parts, allowing for the extent to which the auto index is attributed to original equipment parts.

The writer cannot understand how the FRB arrived at adjustments for the last three years opposite in direction to that clearly indicated by the bulk of the relevant data. Note, however, the FRB statement concerning automobiles: "annual index reviewed by comparison with Census value of shipments data, deflated, for passenger cars" [8, p. S-9]. If that review governs, the auto index becomes just another deflated value series, with the FRB deflator obviously biased downwards, because of its inconsistency with the known quantity and quality data.

Are there exaggerated corrections for changing quality or product composition for other consumers' goods industries? The dairy products and tobacco products groups appear worthy of investigation in this respect.

For consumers' goods as a whole, Gehman has compared the trends of the revised FRB index and of Commerce Department estimates of consumer expenditures, deflated, and adjusted to comparable coverage [2, Chart 3, p. 35]. His chart shows the FRB index rising considerably more rapidly. In fact, the former series increased 64.7 per cent, the latter 45.8 per cent, over

the 13 years 1947-1960. If the Commerce figures are accurate, this indicates an upward bias of 13 per cent for the entire period, or almost 1 per cent per year in the FRB consumers goods index. This is on the assumption that distributive margins, included in the Commerce figures only, remained unchanged during the period. Actually they increased, so the FRB index should show a smaller rise, and the indicated bias is even larger.

V. *The Index as a Whole*

Research by Gehman permits an estimate of the order of magnitude of the over-all bias in the revised index. He has adjusted GNP data and omitted one section of industrial production to put the two on a closely comparable basis for coverage. The resulting Commerce-deflated nonfarm goods output

TABLE 5—ADJUSTED INDUSTRIAL PRODUCTION AND GNP NONFARM GOODS,
IN CONSTANT PRICES, SELECTED YEARS, 1947-1960
INDEX NUMBERS, 1947=100

Year	Industrial Production Excluding Construction Materials	GNP Nonfarm Goods Output Constant Dollars	Ratio of Industrial Production to GNP Nonfarm Goods
1947	100.0	100.0	100.0
1950	113.7	108.1	105.2
1953	140.0	128.6	108.9
1957	154.3	138.5	111.4
1960	166.8	145.5	114.6

Source Note: GNP Nonfarm goods output compiled from [16, Tables VII-6, p. 224, and VII-10, p. 226] and [12, Tables 66, p. 31, and 67, p. 32].

series is charted, together with the revised FRB index, on a base of 1946 = 100. The former falls short of 155, while the latter approaches 190 early in 1960. Gehman comments: "Over the whole 14-year period from the first half of 1946 to the first half of this year the difference in levels approaches one-fourth" [2, p. 44]. However, almost a 10 per cent difference opened up in the very first year, when postwar adjustments distorted many measurements.

The main conceptual difference is in the inclusion of distribution in a major segment of the Commerce statistics, enhancing the discrepancy, in view of the known rise in the relative importance of distribution. The development of the gap between the two series since 1947 has been remarkably steady, as shown by Table 5.

The cumulative divergence of 14.6 per cent for the thirteen years is equivalent to an annual rate of 1.05 per cent per year. Moreover, the rate of divergence is close to 1 per cent per year in each of the tabular intervals, except for the first, where it is slightly higher. The reader will recall that the rate by which the revised index exceeds its predecessor in growth is also about 1 per cent per year.

This is consistent with biases in separate segments of the index, as shown in Table 6. To these should be added biases, if any, in other segments of the index, and biases resulting from overweighting of fast-rising items because of inclusion of distribution and advertising in the weighting base. Consider two major items in the latter category, residential utilities and drugs, soap, and toiletries. The textual discussion justifies the opinion that these items are given at least twice their appropriate weight. If so, 100 per cent overweighting of these two items gives an upward bias of .09 per cent per year to the index. However, part of this is duplicated in weighting the biases shown in Table 6, so the entire .09 per cent cannot be added to the total shown therein.

Among the individual consumers goods items, automobiles, for the four-year interval 1956-60, shows an upward bias of 3.91 per cent per year, which,

TABLE 6—COMPILATION OF MAJOR BIASES, FRB INDEX

Index Segment	Per Cent Upward Bias		Weight	Contribution to Annual Bias in Total Index (per cent)
	Cumulative 1947-1960	Average Annual Rate		
Electricity	17.0	1.21	3.76	.045
Equipment and equipment materials	31.8	2.15	23.72	.510
Consumers goods	13.0	0.94	31.13	.293
Total			58.61	.848

Sources: Cumulative upward bias as shown in text, and Table 2. Weights from [8].

when appropriately weighted, contributes .144 per cent per year of bias to the entire index, or about half of the bias shown for consumers goods as a whole. A substantial portion of the remainder is accounted for by drugs. Calculated on the maximum basis developed in the text, that is, by use of the Drug Topics prescription price index, an average annual contribution of .09 per cent to the bias in the entire index is indicated for the period 1947-1959.

From the varied evidences adduced, the writer believes that substantial upward bias, perhaps of an order of magnitude of 1 per cent per year, is strongly indicated for the FRB index as a whole. But whether more or less than 1 per cent, the important thing is to recognize the existence of a bias and to understand its sources, so corrections can be made.

Gehman believes that the marked discrepancy between the revised FRB index and GNP data stems from errors in the price deflators used by the Commerce Department, and thinks they should be revised downward, resulting in a more rapidly rising real gross national product to conform with the industrial production index [2, p. 44]. It is the writer's conclusion, based largely on the analysis presented herein, that the discrepancy is mainly due to the upward bias in the revised FRB index, which should be changed accordingly.

There is widespread concern over the industrial and over-all economic growth rates, deemed by many to be inadequate in relation to international competition and the rising trend of unemployment. The present FRB index, and an upward revision of real GNP to conform to it, would contribute to a synthetic statistical "solution" to the growth problem, without easing its symptoms, and would tend to ward off actions making for a real solution.

There is concern, and among many a degree of distress, because of the upward "creep" in living costs. A downward revision of the price indexes used in GNP deflation, of which the CPI is the most important, would contribute to a statistical "stabilization" of living costs, without easing the symptoms of a continued actual rise. Moreover, it would be inequitable to those, principally wage and salary earners, whose income rates are either tied by contract to, or influenced by fluctuations in, the consumer price index.

The inconsistency between the revised FRB index and other series should be resolved by indicated revisions in the FRB index as follows:

1. Electric power production should be measured by a single series of all kilowatt hours, instead of by the present set of unevenly weighted series that wholly omit an important section of output. The same correction should be made for gas.

2. Weights for electricity, drugs, fluid milk, and various other commodities which now include a large proportion of distributive activities should be lowered to eliminate these activities from the weight base, even if some estimation is required for the adjustment.

3. Annual series based on deflated dollar value data should be eliminated. All sources of quantity data, even if imperfect and incomplete, should be given priority, and the power and influence of the government should be used to obtain annual quantity data in crucial areas where they are now lacking. Where quantity data are simply unavailable, or cannot be synthesized from materials consumption, or other indicators, man-hours data should be used in preference to deflated values. Deflated values should only be used for supplementary series of unmeasured miscellaneous or new products of an industry. In such cases, a parallel deflator can be inferred from quantity-value relationships of those major commodities for which quantity figures are available.

4. Where indexes are based on a compound measurement of units, with varying weights depending on quality or size specifications, details about the weighting system should be published, and the allowance for quality differentials should be modest. This applies to automobiles and cigarettes, among others.

5. Since 1958 Census benchmark data are already available, a fresh revision of the FRB index, along the lines suggested, can be combined with its adjustment to the 1958 benchmark. At the same time, the criticisms contained herein should be considered in constructing indexes of production from the 1958 Census.

The Revised Index of Industrial Production: Reply

Mr. Perlo's critique of the 1959 revision of the Federal Reserve industrial production index does not make a credible case for the existence of an upward bias in the index. It will serve a useful purpose, however, if it stimulates fresh critical inquiry by the economics profession into problems of analyzing fluctuations and growth in the industrial segment of the economy.

I. Major Considerations as to Output Levels

Index users need to be familiar with the ways that indexes are compiled, and index compilers need to know about the problems of users in various phases of their work. More general understanding of the industrial production index is of increasing importance as it becomes more widely used for such purposes as international comparisons of growth and the study of trends in resource utilization.

Cyclical and growth fluctuations in the commodity-producing industries have continued to play a dominant role in economic activity in recent years. Those of us at the Federal Reserve who work closely on the analysis and measurement of industrial production welcome the opportunity provided by

Perlo's article to comment on major measurement problems in this area and some of their implications for interpreting economic trends.

We can agree with Perlo in underlining the difficulties of deflating aggregates of final expenditures to compile accurate measures of real output and of developing current industry indexes following consistent groupings of activities and products. We also would stress the importance of broadening the nation's information on the physical volume of output and supplies of goods. But we cannot accept his conclusion that the accuracy of production measurement would be improved by giving priority to the use of all sources of quantity data, "even if imperfect and incomplete."

This reply to Perlo's critique is directed mainly to his view that the index has an upward bias of about 1 per cent per year. It comments on his impressions that all features of the 1959 revision operated to raise the growth rate of the index and that special deflated annual indexes developed at that time contributed a major share of the upward revision. It discusses his criticism of the coverage by the index of certain distribution activities, such as those for electricity, and of the inclusion of business services, such as advertising outlays for cigarettes, in the value-added weights. This reply also discusses his criticism of the adjustment for product changes in autos and his general conclusion that the extent of the bias in the total index can be determined in part by comparisons with deflated GNP measures.¹

The question of bias. Perlo's view that the rise in the industrial production index has been overstated is of special interest these days when other analysts are more concerned that existing industrial production measures may not adequately reflect the rapid proliferation of new products in prepared foods, electronics, chemicals, and miscellaneous categories of consumer goods, as well as the sharp expansion in space and missile manufactures and the accelerated development of automatic-control and processing equipment. And the record since the early postwar period has been one of net upward revisions in national data on employment, expenditures, and output, when benchmark data have become available.

This is not to suggest that overstatements in the index cannot develop for the total and especially for particular industries. The apparel industry, not discussed by Perlo, is one important category whose index probably has been too high in recent years. The broad range of industrial materials and products directly represented in the total index—now including over 200 monthly series—provides more limits on the possible development of an over-all bias due to any biases in specific series and weights than existed during the early phases of the index when it included only major materials and a very limited range of intermediate and finished products.

The 1959 revision. The foremost influence on the level of the index in the

¹ Some aspects of the 1959 revision of the index might have been more easily understood if it had been feasible to provide more specific descriptions of the adjustments made in the levels of individual series in the monthly index. The *Industrial Production: 1959 Revision* publication [3], however, already ran to 230 pages of analysis and descriptive and tabular material, including about 90 charted comparisons of series. It was supplemented by the publication of a chart book which showed some 220 individual monthly indexes plotted on ratio scale to facilitate cyclical and growth comparisons.

1959 revision (apart from the addition of the utility industry) was the adjustment to 1954 Census of Manufactures results. These results showed that output of manufactures in the Board's published index on a 1947 weight base was understated, since the index showed a rise of 26 per cent rather than 31 per cent from 1947 to 1954.

Some major decisions made in the 1959 revision operated to lower the amount of the upward adjustment. These decisions included: the selection of more recent weights for the period beginning in 1953, which resulted in less importance being assigned to faster growing industries; the use of the 1957 Standard Industrial Classification for manufacturing that included the slower-growing fluid milk industry; and a correction for undercoverage in the 1947 Census.

The use of special deflated annual indexes to which Perlo refers had relatively little impact on the revision compared to the adjustment to the Census results. The annual indexes provide interpolations between the comprehensive 1954 Census results and those of 1947, and in broad terms extrapolations of output changes for the period since 1954. These annual indexes were compiled to limit the general tendency demonstrated earlier to downward bias in major man-hour and a few physical-product components of the index. Even with the adjustments for productivity changes that had been determined on the basis of the annual indexes calculated in the 1953 revision, the level of output for these components had been understated in the 1951-55 period.

At the time of the 1959 revision it was possible to compile deflated annual indexes from the Census Annual Surveys which were available for the years 1955, 1956, and 1957. Most final data from the 1958 Census of Manufactures have only recently been published. Data on fuel use from the 1958 Census and Annual Survey inventory figures for 1959 needed to calculate output changes from shipments data did not become available until February 1962, the time of this writing.

Consequently, the current monthly indexes for industries represented annually by deflated series are calculated largely from data that have been carried forward from preliminary 1957 levels. For these and other reasons the deflated annual indexes have much less effect on the recent levels of the index than Perlo suggests. In this connection it was observed in the first paragraph of the December 1959 *Federal Reserve Bulletin* article that the revision of postwar levels of growth was "especially from the end of 1950 to mid-1955" [7, p. 1451]. The early part of 1955 reflected some effects of the benchmark adjustments through 1954.

In connection with the Census benchmark as well as the annual deflated indexes there have been no "specially constructed FRB deflators" used for these purposes. The only major departure from the use of official published Bureau of Labor Statistics price indexes (and the unit values implied in the Census) was in the calculation of production data for communication equipment where an unpublished price series supplied by a trade source was used.

It was taken for granted in the description of the 1959 revision that only departures from the use of official sources for prices and other data would be specifically noted. Thus all references to "deflated" in the series table on pages S-4 to S-19 of the *1959 Revision* related to the use only of BLS data.

If there is any misunderstanding on this point, we owe Perlo and other users an apology.

Perlo is properly concerned about the effect of production index adjustments for autos and other types of durable equipment. However, practically all of the net upward effect of the 1959 revision reflected revisions in series for nondurable manufactures and the addition of indexes for the utility industry. The charts in the December 1959 *Bulletin* [7] clearly indicated that there was no appreciable upward revision in the level of durable goods manufactures. Yet the durable goods portion of the total index involved about two-thirds of the deflated annual sources shown in Perlo's Table 1.

1954 Census benchmark. The Census benchmark analysis, rather than the deflated annual indexes, was so basic to the 1959 index revision that its results might have been expected to be the primary object of Perlo's critique (see *Indexes of Production*, Census of Manufactures, 1954 [5]). That document is an important item, and knowledge of it is essential to an understanding of the basis for the adjustments in the levels of series and certain other aspects of the 1959 index revision. It (together with its 1947 Census predecessor) is a unique, authoritative source of material on real economic growth in the industrial segment of the economy. If any improvements in the analysis could be developed, they would be of value in the determination of the next set of benchmark indexes to be calculated from the 1958 Census of Manufactures.

There was a general effort in the development of the 1954 benchmark to extend the use of direct quantity measures. As shown on page 16 of the Census volume, 86 per cent of total manufacturing output was represented by industries for which physical quantity data were available, compared with 75 per cent in the 1939 to 1947 calculation, and about 60 per cent for the earlier Census index calculations.

The remaining industries in the 14 per cent area of "indirect representation" were those for which no homogeneous units of physical output were available, and included those making a wide miscellany of consumer goods, commercial printing, scientific instruments, and miscellaneous metal fabricated products. The decision to use deflated values in most of these industries was made after statistical tests with the "directly represented industries" had shown that this approach would probably result in a smaller error than an assumption that their productivity changes had been similar.

Perlo is mistaken in indicating (p. 4) that the industrial production index makes no allowance for output changes in an industry when they differ from changes shown by the primary products of the industry. The use of "coverage adjustments" has been a regular feature of the benchmark calculations for many years, and these were further refined in the 1954 Census volume.

Changes since 1954. The remaining portion of the question of possible overstatement in the industrial production index relates to the period since the 1954 benchmark. Until additional benchmark results for the 1958 and 1963 Censuses of Manufactures are available no final conclusions on this question for the whole period are possible.

Since Perlo is willing to accept the evidence of "all sources of quantity data," the changes shown by the physical product series in the monthly index

are of interest. (These are described and charted in the *1959 Revision* [3, pp. 22-24.]) The average level of these series rose 9.1 per cent from 1954 to 1958, as compared with 8.8 per cent shown by the total index. For the whole period from 1954 to the beginning of 1962 the rise was about 33 per cent for physical products and 34 per cent for the total index.

Despite Perlo's faith in quantity data per se, it should be emphasized that during some critical periods, such as 1951-52, activity in certain major industries such as aircraft and machinery, for which there are no adequate monthly physical product data, has moved quite differently from activity in industries producing metals, textiles, and many consumer goods where monthly product data are available. In recent years, output of steel, fuels, and some of the other major items in the physical product portion of the index has been relatively low. Meanwhile, activity in the electronic, chemical, and space product industries has expanded sharply so that again in this period the physical product series may not fully indicate the course of the total industrial production index.

The results of broad comparisons based on man-hours worked, industrial electricity consumption, freight movements, output of major industrial materials, and deflated manufacturers' shipments of goods do not indicate any major shifts since 1954 in their longer-run relationships to the output index for manufactures or to the total index. The level of the total index, for example, increased relative to total BLS production-worker man-hours for manufacturing, mining, and utility industries by 37 per cent over the benchmark period 1947 to 1954, while from 1954 to 1961—another 7-year interval—the indicated increase was 36 per cent. In fact, however, there may have been some acceleration in the actual rate of increase in recent years.

II. *Other Aspects of Measurement*

Detailed comments on each of Perlo's criticisms are not being undertaken in this note, but comments on some of them seem to be merited.

Coverage considerations. Problems of industry definition necessarily involve some rather arbitrary solutions; and the continued growth of industrialization tends to widen the defined areas of manufacturing. A major consideration for measurement purposes is the importance of avoiding any significant duplication of activities among industrial establishments and between industrial production and activity measures for other segments of the economy.

In the 1954 Census and the 1957 version of the SIC there were several instances of a widening of the coverage of manufacturing activities. Among the additional activities included were the processing and distribution of fluid milk. Appropriate adjustments were made for this change to maintain comparability in the Census and industrial production figures. The effects in the 1959 revision of adding the series for fluid milk, including the distribution activity involved, were not negligible since it has a weight of 1.1 per cent of the total index and it has risen much less than the total index since 1947.

Electricity distribution. The coverage of electricity and gas distribution by the index appropriately follows from the scope of the activities repre-

sented in this segment of the economy according to national standards (SIC #491-3) and usual practices in foreign countries, as defined in group #51 of the International Standard Industrial Classification. (Perlo has erred on this point in quoting from a summary section of the United Nations report *Index Numbers of Industrial Production* [4, p. 7], rather than from the relevant section in that report on scope and grouping [4, p. 10].)

It is true that the representation of electricity generation and its distribution to residential customers may be questioned on the ground that the index should be limited to the traditional products of manufacturing and mining. Both electricity and gas, however, are materials and their representation in industrial production of consumer goods seems to us less subject to question than their inclusion as consumer services in measures of prices and of outlays.

As Perlo suggests, there is some basis for differences of interpretation regarding the precise allocation of estimated value-added figures for the separate classes of electrical and gas utility sales represented in the index. From the critical viewpoint of economic analysis there is much to be said for distributing the importance of the value-added figures approximately in relation to the revenues involved for each class of sales. Even if it were proper to count electric kilowatt sales (and gas therms) equally, such a change would reduce the current level of the total index relative to 1947 by only .5 per cent.

Industrial generation. Another question raised by Perlo on electricity relates to the desirability of compiling and including separate production series for industrial self generation. To allocate self-generation output by 3-digit SIC industries would involve the calculation of many additional monthly indexes. However desirable additional detailed series might be in such industries as chemicals, paper, and primary metals, which are among the main self-generators, they would have little effect on the movement of the total index. Self-generation is estimated to account for less than .5 per cent of total industrial value added in 1957 and in the present index this value added is assigned to the movement of directly represented production series. Over the period from 1947 to 1959 the total index rose 61 per cent, compared with an increase of 60 per cent in self-generation, as noted in the *1959 Revision* [3, table and footnote p. 17].

In this connection and with a view to strengthening the current monthly series on industrial production, the Federal Reserve System has inaugurated in recent years a national project to compile electric power consumption data by standard industry classifications of manufacturing and mining groups of establishments. These data will include monthly figures on self-generated power and on sales by electric utility companies to industrial establishments. Already this information is beginning to yield supplementary results which at times help to interpret movements in other measures.

Miscellaneous business services. With regard to the inclusion of advertising and other business services in the value-added weights for the production series, they apparently have little over-all influence on the movement of the total index. In the case of cigarettes, it is true that a reduction in their im-

portance (relative to cigars) would result in less rise in the tobacco products group, but with the importance of cigarettes reduced, the total index would rise more because cigarettes have risen less than the total.

Perlo mentioned only advertising expenditures, but manufacturers' outlays for contract repairs and professional fees are even larger. The differential effects on weights of these various purchased services, including advertising, within the industrial total are largely offsetting as discussed in the weight section of the *1959 Revision* [3] and in the 1954 Census benchmark volume [5, p. 27].

Adjustments for product changes. Ridicule of "fins" on autos and eye-catching pronouncements about other aspects of our affluent economy may have diverted economists in this country from giving more serious attention to the subject of real changes in production and prices. Broadly viewed, from the early postwar years of ersatz products, general shortages, and excessive demands for goods to the situation in recent years of ample available resources and technologically advanced levels of industrial operations, there have been many logical and empirical grounds for noting a general improvement in the product characteristics of goods available.² The development of strong, competitive pressures on output and prices, including the sharply expanded supply of cheaper foreign goods, has been an important consideration in interpreting economic trends over the postwar period.

More intensive efforts to isolate product changes in price indexes from 1945 to 1961 would probably still leave most deflated output measures too low. For this reason, too, and because some output measurements are still based only on the weight of materials involved or simple numerical counts of various complex products, the production index probably provides a minimum statement of the rate of industrial growth both before and after 1954.

Perlo quotes with approval Milton Gilbert's references to "flights of fancy" corrections for index price changes which "would give doubtful results when transferred to the production index" [2]. Gilbert's conclusions may be pertinent to such style items as ladies' hats, but some of the examples he cited, such as more durable cloth and tires of greater mileage, certainly do have measurable implications for changes in employment and productivity rather than the "absurd results" suggested by Gilbert. One of the practical approaches to the problem of measurement of product changes is to be found in the use of more detailed breakdowns as in the case of textile fabrics, home freezers, tractors, and electric generators, as noted in the description of the 1959 revision.

Motor vehicles. It is gratifying to note that Perlo agrees with the principle of drawing on available data to make at least a partial adjustment for changes in specifications for passenger automobiles. Since the beginning of 1960, as a result mainly of the shift to compact cars, no further upward adjustment for

² In addition to last year's Congressional hearings, *Government Price Statistics* (Hearings before the Subcommittee on Economic Statistics, Joint Economic Committee, 87th Cong., 1st sess., Pt. 1, January 24, 1961), which contain many references to the price deflation problem, a recent article of interest is by Murray Foss [1].

changes in specifications for autos has been made in the published monthly production index. Using the product specifications provided by Perlo, the auto assembly series seems to have been overstated in the 1958-60 period relative to 1956-57. However, the trend of changes in auto specifications since 1958-60 also needs to be taken into account to judge the adequacy of current output levels. For example, important improvements have been introduced in the 1961 and 1962 models, including compacts, such as additional equipment, better lubrication systems, self-adjusting brakes, and the like, so that the current level for the auto series is not necessarily too high relative to 1956 and earlier periods.

The development of independent measurements of passenger-car characteristics received attention in the material developed in last year's Congressional hearings on Government Price Statistics. A recent updating of one of these studies by Zvi Griliches using nine specification variables relating to the three major low-priced autos was made in a paper presented at the 1962 Conference on Research and Wealth of the National Bureau of Economic Research. This study showed a further rise in "quality" adjustments for the period as a whole from 1956 to 1960-61, while Perlo's calculated corrections declined 5 per cent from 1956 to 1960. This is a subject on which the engineering talents and staffs of the auto companies might well make a major contribution.

In reviewing the figures for the auto series it is necessary to consider also the adequacy of the index measurements for the total volume of goods produced by the motor vehicle industry and the effects of auto product changes on other industries. Thus, a major part of the impact of the shift in the size and weight of vehicles is reflected in other sectors of industrial production such as the glass, steel, and textile industries. The production index measurements are designed to reflect the total contribution of the motor vehicle industry, so that in addition to the auto assembly series there are involved the production series for replacement and for original equipment parts, and for trucks and other products of the motor vehicle establishments. These series are also difficult to establish with accuracy and in some cases have an important downward bias. For example, there is no allowance in the index for the marked gains in performance of late-model trucks compared with those produced in the period immediately after the Second World War.

Deflated GNP comparisons. Perlo makes several references, which are probably of general interest, to the results of confronting industrial production indexes with GNP constant-dollar measures. At one point he cites a comparison of industrial output of consumer goods with personal consumption expenditures for goods in a paper presented by the author at the 1960 annual meetings of the American Statistical Association [8]. That comparison of the monthly production series with the quarterly expenditures data was made to illuminate differences in the cyclical behavior of the two series. Any attempt at an exact accounting of differences in growth trends for these two measures would involve a variety of considerations, including coverage and weight influences, that cannot be adequately discussed here. The effects, however, of a decision by the compilers of the gross national product data

not to accept the results of the Census benchmark flow figures for the year 1954 relative to 1947, but to scale them down by $1\frac{1}{2}$ per cent (*U.S. Income and Output*, 1958, [6, p. 75]) should not be overlooked in such a comparison. This percentage was related to the total figure for personal expenditures on goods and services in 1954 and the difference might be more or less than that percentage for the gross factory value of consumer goods alone.

The comparison of differences in the GNP and production-index series for equipment indicated in Perlo's Table 2 is certainly worthy of further analysis and much more detailed attention than is possible in this note. As he suggests, the differences between these series cannot be pinned down exactly, so that the shifts shown between 1947 and 1953 may not be too significant. The presence of large differences since 1953 was noted in the *1959 Revision* publication and attributed partly to the difficulty of taking into account product improvements when price indexes are used to deflate estimated outlays for equipment. Perlo concludes that it was unlikely that a difference in actual prices could be much of an explanation, because he said there was an increase of 5 per cent in the Commerce deflator between 1957 and 1960 which would explain only half of the discrepancy between the output and expenditure series. In such a period, however, actual prices could decline as well as continue unchanged.

Perlo states in his conclusion that deflated dollar value data should be eliminated from the annual production series and that product data or even man-hour data should be used in preference. This statement is hardly consistent with his use of deflated GNP data to calculate a quantitative measure of the extent of upward bias in the production index, as shown in Table 6.

Only one illustration need be given of his handling of the price aspects of the deflation problem. In a section on drug price changes from 1947 to 1959 he cites a decline of 10 per cent in the BLS wholesale price index, a rise of 23 per cent in the consumer price index, and an increase of 108 per cent in prescription prices from a trade source. He concludes that the last change is the most realistic and that such a retail price series for prescriptions prepared in a drugstore would be an appropriate deflator for factory values of basic medicinal items!

No real solution of questions of bias in price series or in the production index can be accomplished by the simple expedient of adjusting any set of numbers to the level of another. Readers will find no support in the source cited by Perlo [8, p. 117] for the view that real GNP should be raised to conform with the industrial production index. The GNP constant-dollar series may be too low because of the assumptions used regarding productivity changes and for other reasons, in addition to problems of price deflation, but the course of industrial production by itself does not demonstrate such a conclusion.

Some problems of real product measurement are statistically insoluble and even continuous, close review of issues relating to classification, representation, series, and weights cannot assure perfectly exact production indexes either currently or at benchmark intervals. Further refinements in the

production indexes are desirable and possible, and additional critical attention to these and other economic measures is likely to contribute to improvements in both the data and their interpretation.

The Bethlehem-Youngstown Case and the Market-Share Criterion: Comment

In a recent communication in this journal [8] Lucile Sheppard Keyes expressed a fear that the market-share concept will have a role of "great practical significance" in the treatment of horizontal mergers. She is afraid that the courts will interpret the amended Section 7 of the Clayton Act so as to prohibit only those horizontal mergers that "would combine suppliers of 'large' percentages of the output of some 'product,' or would increase the share of the 'product' accounted for by a firm with an already 'large' existing share" [8, p. 644]. Mrs. Keyes finds support for this prediction in the district court's opinion in the Bethlehem-Youngstown case. She suggests that the best available course might well be "to prohibit mergers between firms significantly competitive with one another," [8, p. 654], rather than to prohibit those mergers that may substantially lessen competition or tend to create a monopoly in any line of commerce in any section of the country as judged by the effect of the merger on the market share of the acquiring company.

The purpose of this note is to take issue with Mrs. Keyes's conclusions on

two grounds: (1) several recent cases indicate that her pessimism about the effectiveness of the market-share criterion in stopping horizontal mergers is unwarranted, and (2) the alternative criterion she suggests would very likely achieve no better, if not worse, results.

I. The Market-Share Criterion in Other Cases

The use of the market-share criterion has already resulted in a number of Federal Trade Commission and lower court decisions to stop or dissolve horizontal mergers that clearly would have been allowed under either the old Clayton Act (if they had been stock acquisitions) or the Sherman Act.¹ The markets have been defined very narrowly both with respect to the line of commerce and the section of the country, and the condemned market shares in some cases have been quite small compared with those applied in Sherman Act cases. Mrs. Keyes, herself, in discussing Bethlehem-Youngstown [8, p. 647] says:

On the other hand, it must be admitted that the percentages at issue in this case, while large as compared with the negligible share attributable to the member of a pure-competition industry, are small compared to the shares considered significant in Sherman Act cases. . . . This relative smallness becomes more impressive when it is noted that the proposed merger was found to be (prospectively) in violation of the statute in *each* of the markets considered.

This observation does not, however, allay the fears of Mrs. Keyes, who goes on to say:

The essential point is, however, that some minimum share may be crucial in the law's application; furthermore, what may be large enough for one judge may be much too small for another.

The share of the market that is used, however, must be considered in conjunction with the breadth of the definition of the line of commerce and the section of the country. In the Bethlehem-Youngstown case the district court was willing to declare the merger unlawful on the basis of proof of substantial lessening of competition in a market as small as that of "hot rolled bars" in Ohio [8, p. 647]. Citing this case as a precedent, Judge Weber, in the Brown Shoe Company case [11, p. 736], found a relevant market by which to judge the acquisition of the Kinney Company by Brown to be the retail market for shoes in any city in the country in which a Kinney store and a Brown store are operated.

In the Erie Sand and Gravel Company case the Federal Trade Commission distinguished between "lake sand" and "pit or bank sand," and defined the market geographically as a strip along the southern shore of Lake Erie extending twelve miles inland. This decision was reviewed by the Third Circuit Court of Appeals, which rejected the distinction between lake and pit sand

¹ Before the 1950 amendment to Section 7, the Clayton Act applied only to the acquisition and continued holding of the stock of one corporation by another. Mergers of any other type were subject to scrutiny by the Justice Department under the general prohibitions of the Sherman Act. See [9, pp. 104-23, 268-72].

[4]. The court, however, recognized that the high transportation cost of sand prevents lake sand from effectively competing with pit sand very far inland. In arguing the case on appeal, the Commission's attorneys substituted eight discontinuous areas around the port cities for the continuous strip. It was on this ground that the court remanded the case to the Commission for further consideration. Significantly, however, the court said that "the government's proposed definition of the relevant market area is not on its face inconsistent with anything in Section 7 of the Clayton Act."

The Ninth Circuit Court of Appeals recently reviewed another decision of the Federal Trade Commission, in which the Commission ordered Crown Zellerbach to divest itself of the assets of the St. Helen's Pulp and Paper Company [5]. Since this was the first case to be decided on its merits by the Commission and the first to be finally reviewed by a Court of Appeals, it is likely to become an important precedent and needs to be considered carefully in evaluating the new statute.

The Commission decided that the relevant line of commerce was "coarse paper" as defined by the Census Bureau, although the respondent urged the inclusion of other types of paper products [6, p. 3]. Crown Zellerbach argued that the relevant section of the country should be the whole United States, or at least the part west of the Mississippi River. The Commission decided instead to use the eleven western states on the grounds that sales made in that area by producers located to the east were "relatively insignificant." With the relevant market thus defined, there were only ten producers in the market, and during the year of the acquisition the market shares of Crown Zellerbach and St. Helen's were 51.5 and 11 per cent, respectively.

The court upheld the decision of the Commission, but it went even further in narrowing the definition of the market. The court added "manufactured bags" to "census coarse papers" as the relevant line of commerce, but it ruled that the three Pacific Coast states were the proper section of the country. The court explicitly stated that "the line of commerce need not even be a large part of the business of any of the corporations involved." Furthermore, the Ninth Circuit Court of Appeals gave its sanction to Judge Weinfeld's distinction between the Sherman Act criterion on monopolizing and the new Clayton Act criterion by quoting with approval this statement from the Bethlehem opinion [10]:

... when the question is power over price, substitute products may be relevant because they can limit that power. The issue under Section 7 of the Clayton Act is not whether a merger may result in a company having power over price or the power to exclude competition. The issue under Section 7 is whether there is a reasonable probability of substantial lessening of competition.

The ultimate test of the meaning of the standard of legality contained in the amended Clayton Act will come only when a series of cases have been decided by the Supreme Court. These two Circuit Court of Appeals opinions, however, indicate that a policy is evolving that will prohibit horizontal mergers among firms competing in *any* market so long as the resulting concentra-

tion of control in such a market is sufficient to convince the judge that a tendency toward monopoly or a substantial lessening of competition may result. Mrs. Keyes objects to the use of such a criterion because it requires the application of a rule of reason that may result in the statute prohibiting only those acquisitions that involve firms with large market shares.

Furthermore, she sees a contradiction inherent in the statement of Judge Weinfeld that the issue is not, under the Clayton Act, "whether a merger may result in a company having power over price or the power to exclude competition." She points out [8, p. 646] that a more expedient way around the Cellophane doctrine would have been simply to have accepted the relevance of substitute products and required a smaller share for a violation of the Clayton Act because

. . . the argument used here tends to undermine the entire orthodox rationale for the consideration of market shares in merger cases: If "the power to control prices or exclude competition" is not at issue under Section 7, then why invoke the elaborate apparatus of market definition and percentage share computation which is alleged to be specifically designed to measure "market control" or "monopoly power"—i.e., the power to control prices or exclude competition?

Ambiguous as it may be, Judge Weinfeld's reasoning can be defended on these grounds: Congress clearly intended that the new Clayton Act standard of illegality be such as to prohibit some mergers that would be allowed under the Sherman Act test. The Sherman Act test required the plaintiff to demonstrate the relevance of a market defined in terms of products to be included as well as in terms of some geographical limitation. Within such a market the share of the accused firm had to be large. A body of precedents exists for evaluating *all three* of these aspects of a case at bar—particularly the Alcoa, Columbia Steel, and Cellophane decisions. In enacting the new legislation Congress was instructing the courts to depart from the existing precedents in the direction of prohibiting more mergers. Why should the change be made only with respect to market shares? Economists certainly have no objective method of delineating a market. A subjective value judgment must be made. Congress was dissatisfied with the judgments under the Sherman Act, but the Celler-Kefauver Act provided no new method of making decisions. It simply called for value judgments by judges and the Federal Trade Commission that would place a lighter burden of proof on the government than the Sherman Act required in merger cases. In effect, Judge Weinfeld and the Ninth Circuit Court of Appeals, have decided to implement the new Congressional policy by providing new precedents that change the law with respect to the definition of the product and the section of the country as well as the magnitude of the market shares required for conviction. It is, of course, true that the Bethlehem-Youngstown decision does not provide a *rule* for market definition that is "any more objectively determinate . . . than that which would be appropriate under Section 2 of the Sherman Act" [8, p. 646]. But it does provide a *precedent* that will serve to make it easier for the government to stop horizontal mergers.

In the recent Clayton Act cases the courts have shown their willingness to prohibit mergers with horizontal aspects on the basis of a showing that previously independent suppliers of some clearly defined and well recognized product to customers in some geographical area recognized as a trade area have been joined by the merger, even though their market shares are small as compared to the Sherman Act precedents. Is this not what Congress intended? What are the alternatives to such a case-by-case examination of the effects of a merger on the structure of control of the relevant markets?

II. *The Keyes Criterion*

Mrs. Keyes suggests that "... to prohibit mergers between firms significantly competitive with one another might well be the best available course." She recognized that such a criterion raises a conceptual problem of defining "significant competitiveness," saying [8, p. 654]:

It is necessary to draw a definite and defensible line between the competitiveness which will make a merger subject to legal control and the general competitiveness between each pair of firms in the economy; and the rough distinction between "potential" and "actual" competition is not sufficiently precise to serve this purpose.

Mrs. Keyes, therefore, further suggests [8, p. 654]:

... that the legal test of significant competitiveness among merger participants be satisfied by showing that some nonnegligible amount of dollar revenues of one participant is accounted for by sales for which buyers would have substituted the other participant's product, had it been offered at the lowest cost-covering price, if the actual seller had withdrawn his supplies.

Although this line is reasonably precisely drawn conceptually, it would be extremely difficult for the Justice Department or the Federal Trade Commission to prove its allegations with substantial evidence. Just as the court must now decide subjectively on the relevant market and the effects of a market-share increase, it would have to speculate about what buyers would have done if things had been different. Furthermore, the judge would have to decide what constitutes a "nonnegligible amount of dollar revenues." Would this be interpreted to mean a "substantial amount"? If so, we would return to a criterion of illegality very similar to that used by the Federal Trade Commission and the courts in interpreting the original Section 7.

I have argued elsewhere [9, Ch. 3-5] that it was this interpretation of the language of the statute rather than the so-called assets loophole that really emasculated the statute. The original Section 7 of the Clayton Act prohibited a stock acquisition [2].

... where the effect of such acquisition may be to substantially lessen competition between the corporation whose stock is so acquired and the corporation making the acquisition, or to restrain such commerce in any section or community, or tend to create a monopoly of any line of commerce.

Thus, the "substantial lessening of competition" part of the criterion applied to competition between the parties to the merger rather than to competition in a market.

In the first court test of the meaning of this language in the 1922 Alcoa case [3, p. 409], a majority of the Court of Appeals held that, since the law contemplated potential competition, it was not necessary to prove that the two companies actually had been in competition with each other before the acquisition. One judge, in a dissenting opinion, argued that competition between the firms must have existed for the law to be violated. The latter interpretation became the law after the Supreme Court opinion in the International Shoe case in 1930, which said [7, pp. 297-99]:

Thus it appears that in respect of 95 percent of the business there was no competition in fact and no contest, or observed tendency to contest, in the market for the same purchasers; and it is manifest that, when this is eliminated, what remains is of such slight consequence as to deprive the finding that there was substantial competition between the two corporations, of any real support in the evidence. . . .

Mere acquisition by one corporation of the stock of a competitor, even though it results in some lessening of competition, is not forbidden; the act deals with such acquisitions as probably will result in lessening competition to a substantial degree . . . that is to say, to such a degree as will injuriously affect the public. . . . If it be conceded that the entire remaining 5 percent of each company's product (although clearly it was materially less than that) was sold in competitive markets, it is hard to see in this, competition of such substance as to fall within the serious purposes of the Clayton Act.

The Court thus judged substantialness in terms of the share of the total business of the two firms that was done in competition with each other, rather than the shares of the total sales in any particular market that were in the hands of the two parties to the merger. As a result of this decision, the Federal Trade Commission adopted the policy that the public interest is best served by preventing mergers between companies that displayed a substantial proportion of their business in competition with each other irrespective of the structure of control of the particular markets in which they operated [9, Ch. 5].

The Celler-Kefauver Act, by changing the language of the criterion of illegality of Section 7, superseded the pre-1950 Clayton Act precedents. By including asset acquisitions, the 1950 legislation superseded the Sherman Act precedents. A new body of law on mergers is now being evolved. Mrs. Keyes's proposal would allow the courts to draw upon the old Clayton Act precedents by refocusing on the relationship between the merging firms. Where two firms sell some product in a particular section of the country, the effect of their merger does not necessarily depend on how much they sell of other products in other markets. But a court might well look to just this sort of evidence in evaluating the substantialness of the revenues of one participant from sales for which buyers would substitute the other participant's product. Such a merger might be classified as conglomerate, and thus be

beyond the scope of Mrs. Keyes's discussion. Yet it would be a horizontal merger from the standpoint of the market in question. It would be difficult to find a horizontal merger, if we defined that term to include only mergers between firms all of the sales of each of which are in the same markets as the other.

The suggested change in the law would not avoid the disadvantage of having to submit to judicial determination questions of fact very hard to discover by objective examination. The rule of reason would remain, and the results might very well be a less economically meaningful administration of the antimerger law.

The Bethlehem-Youngstown Case and the Market-Share Criterion: Reply

Mr. Martin's criticism of my proposed criterion seems largely based on two misunderstandings, which I hope now to correct. The first misunderstanding is the assumption that the phrase "nonnegligible amount of dollar revenues" could be interpreted as referring to a proportion of the total sales of the participant firms, and the second is the assumption that the determination of this amount would be left up to the judges.

The only purpose of the word "nonnegligible" in this criterion is to serve as a supplement to, or perhaps even as a substitute for, the exemption for very small firms, which was suggested on the following page. If the resources

used up by the Department of Justice, the federal courts, and private antitrust litigants were free goods, there would be no justification for either of these limits, which are designed simply to insure that effort is directed along lines of apparent maximum benefit. The dollar amount should be determined, after an empirical study of past mergers, with a view to inclusion within the law's reach of as many anticompetitive mergers—beginning at the top of the size range of affected sales and proceeding downward—as the budget of the Antitrust Department could accommodate without encroaching on more urgent uses for public funds, due account also being taken of the costs to the courts and private litigants. This minimum should be either written into the law as a dollar amount, with provision for periodic amendment to take into account changes in the price level and other relevant variables, or administratively determined, at appropriate intervals, subject to Congressional review.

Martin also observes that "the suggested change in the law would not avoid the disadvantage of having to submit to judicial determination questions of fact very hard to discover by objective examination." It is probably unrealistic to expect to develop antitrust criteria capable of being administered by computers. However, it does not seem impossible so to state my proposed criterion that well over 50 per cent of the judges would agree on the result of its application to any given set of facts. I am indebted to Martin for a constructive suggestion in connection with this drafting job: that is, that the criterion be rephrased to omit the offending "would have substituted," so that what would be required would be a showing that some (specified) nonnegligible amount of dollar revenues of one participant is accounted for by sales for which buyers *could have substituted the other participant's product*, had it been offered at the lowest cost-covering price, *without by this substitution their suffering financial disadvantage as compared with the next best remaining alternative*, had the first participant's product been withdrawn.

It is almost certain that other improvements can and should be made. The development of a generally acceptable formulation for this criterion could represent a very important advance in the clarification and effective enforcement of antitrust policy, which are essential elements in the continuing success of an economy of regulated private enterprise.

BOOK REVIEWS

General Economics; Methodology

Theory of Industrialism: Causal Analysis and Economic Plans. By JOHAN ÅKERMAN. Lund: C. W. K. Gleerup, 1960. Pp. 332. 25 SKr.

This volume is considerably more than a theory of industrialism in the usual sense; rather it represents "a modified synthesis of forty years of research" (p. 8) summarized under five main headings. First, the "Driving Forces of Industrialism" are presented, including technological progress, increase in population, changes in motivation, political change, development of credit, business agglomeration, organization of labor, and changing distribution of income. Second, "Cycles" are discussed, with seasonal, agricultural, political, industrial, and building cycles distinguished. Third, "Structural Change" is considered, in terms of structural indicators, structural limits, and structural lability, as well as in relation to cycles, growth, and innovation. Fourth, "Principles of Economic Planning" are presented, including micro-plans of consumers and producers and macro-plans for full employment and general welfare. Finally, "Causal Analysis and Plans" are analyzed, with discussions of the dualistic principle, problems of summation and causality, and the relevance of economic theory.

I have summarized the volume rather mechanically because I am not sure that I fully understand the underlying logic of Åkerman's presentation. The first section on the forces fostering industrialism, considered separately, argues that, of the eight forces involved, technological progress "is the only autonomous force in the epoch of industrialism" and that the "scientific and technical urge is mainly the result of 'idle curiosity' (Veblen)" (pp. 212, 213). Whatever its merit in Veblen's day, this approach does not seem to me to be adequate at the present time; in fact, in my opinion the rate of technological change is an important—perhaps even the most important— inherent attribute of an economic system. Because he considers it autonomous, Åkerman does not appear to consider technological change in need of explanation, so that his treatment is descriptive rather than analytical. In addition, there is little discussion at any point of the role of capital formation; it is, for example, given hardly any consideration in connection with the development of credit, as the "essential task" of the credit system is stated to be "the bridging of the gap in time, which separates the starting and the *completion* of work on new means of production" (p. 63; my italics).

The discussions of cycles and structural change raise further problems. Åkerman's conclusion is that "*The causes of economic periodicity . . . lie outside the economic sphere*" (p. 178; his italics). He reaches this result by starting with a seasonal cycle of a half-year or a year and an agricultural cycle of two years, which depend on the character of the solar system; arguing for a political cycle of four years (replacing the usual Kitchin or in-

ventory cycle), which he relates to the timing of U.S. presidential elections; and ending with an industrial (or Juglar) cycle of 8 years and a building cycle of 16 years—so that “each period except the basic short season, can be regarded as built on two of the cycles of half its length” (p. 175). The importance Åkerman attaches to the timing of our elections I find flattering, but I cannot say that I find the political cycle or so neat a geometric increase in the length of cycles particularly convincing.

Åkerman also believes that “secular movements of prices are a direct function of the alternation between war and peace” (p. 214). This in turn permits him to reach the basic over-all conclusion that “The *causal* factors of economic growth and economic variations are . . . *exogenous*—they are to be fetched from ‘outside the billiard table’: technology; the rotation of the earth; and wars” (p. 214; his italics). I believe that Åkerman’s emphasis stems from a desire to stress that industrialism involves changing relationships over a broad range. He states, for example, that “fundamental changes—development as well as all sorts of cyclical movements—are actually nothing else than structural changes” (p. 210)—by which I take it Åkerman means social change broadly conceived. But if the interrelated character of the process of change is being emphasized, then it seems inappropriate to treat technological progress, or even wars, as entirely exogenous, or to place so little stress on the economic causes of cycles.

Perhaps what has been said is unfair to Åkerman; perhaps I have concentrated too heavily on the aspects of the discussion about which I had reservations. The volume did, in fact, contain a number of interesting insights, but over-all I must admit that I did not find it particularly enlightening.

HENRY H. VILLARD

The City College of New York

L'économie du XXIème siècle. By FRANÇOIS PERROUX. Paris: Presses Universitaires de France, 1961. Pp. 598. NF 24.00.

An attentive reader of the economic literature in the English-speaking world and on the Continent cannot fail to observe an increasing degree of separation between the two. With the exception of the economists of a few smaller nations who write in our language, there is relatively little exchange of ideas between Continental economists and their counterparts in the United States or in England. And as far as there is a flow of ideas, this goes mostly in one direction: from here to Europe.

One frequently encounters statements to the effect that the counterflow of ideas is unnecessary—even undesirable—since by our standards many economic writings on the Continent are overly verbose and lack rigor. And since so much (or perhaps too much) is published in English, who can take the time to read German quasi-metaphysical expositions or French politico-economic tracts? Yet one cannot help wondering whether this is a satisfactory explanation. Perhaps we should put at least part of the blame on the inability of the vast majority of U.S. economists to read foreign languages—barely disguised by the compulsory requirements in most graduate schools

of a reading knowledge of French and German. (One has only to read some of the language examinations taken by graduate students to know that precious few will ever take a French or German journal into their hands.) Also, one can refer to the tendency towards increasing compartmentalization of the social sciences in this country, well-illustrated by the changeover from the term "political economy" to "economics," while time has not done away with the French *économie politique*.

These reflections are especially appropriate in a review of François Perroux's *L'économie du XXIème siècle*. This book covers a wide range of topics and presents an interesting and illuminating survey of various questions of interest to the Continental economist at the outset of the second half of this century. This is not to say that Perroux's book would merit unqualified praise. Although the uneven quality of the writing and frequent repetitions can be explained by the fact that the volume brings together twenty-seven papers written for various professional and nonprofessional journals over a period of ten years, one may criticize the sometimes oblique references to other authors and the cavalier treatment of several topics. Still, one cannot help admiring the broad sweep of ideas and the refreshing insights offered on a wide variety of problems.

The general theme of the contributions is the author's endeavor to reformulate received theories in view of their application in the context of dynamic change. The fire of Perroux's criticism is directed at the preoccupation of much of our economic theory with static equilibrium positions, and at generalizations concerning the balanced growth of economic structures. As regards the first issue, Perroux dispenses with the assumption of economic units being price-takers—not to build a static theory of monopolistic market-structures, but rather to emphasize the expansionary forces operating in the framework of the large firm. These include the firm's innovating and investing activity, the role of advertising in the creation of new demand, and the tendencies towards horizontal and vertical integration.

The discussion of the place of the dominating firm in a growing economy brings Perroux to the examination of power relations on the international plane. Although the United States no longer meets some of the criteria of the "dominating economy," the emergence of the European Common Market as a new power in the world economy bears out many of Perroux's conclusions. The experience of the Common Market shows for example that the "domination effect" does not refer simply to greater bargaining power, but involves significant repercussions on trade and capital flows as well. Finally, we should note the emphasis on the salient role played by international companies (poetically called *les grandes unites pluriterritoriales*) in economies dependent on industrialized nations, and also in shaping international trade flows.

Perhaps the most important part of the book is the discussion given to the "poles of development." Instead of viewing economic growth as the balanced development of various industries and regions, Perroux expounds the thesis that the growth of an economy depends on the existence of the poles that are created by a key industry and other industries related to it. The concept of the pole of development, as understood by Perroux, is broader than that of

agglomeration economies because, besides the consideration of price-cost relationships, it also encompasses induced technological change as well as noneconomic factors. Perroux maintains that economic development is greatly influenced by the creation of a "growth mentality," attributed to the emergence of a key industry. At this point we should also note that empirical research on the Continent has done much to show the realism of this conception, e.g., in connection with the discussion of the poles in the French or the Brazilian economy.

These are some of the highlights of the book this reviewer found most interesting. Other readers might emphasize different points but it is obviously impossible to do justice to the richness of ideas that characterizes this volume within the space of a short review. There is plenty of material here which can, and should, affect theoretical discussion and empirical work. And although many of these ideas need further development, this should not be a drawback but rather an inducement to future research.

BELA BALASSA

Berkeley, California

Comportement économique et structures sociales. By ANDRÉ NICOLAÏ. Paris: Presses Universitaires de France, 1960. Pp. viii, 322. NF 16.00.

In this theoretical study the relationship between economic behavior and social structures is analyzed in three parts. In the first part, the author examines the nature of systems and coherent complexes of structures; in the second, the significance of economic behavior is discussed; in the last part, the dynamic union of structures and of behavior is explained and evaluated. An interesting preface by Professor Jean Lhomme of the University of Paris introduces the author.

As the title of the essay implies, the author uses a rather broad approach. He argues that our time is no longer that of the "pure economy." Perhaps, the time of the "humane economy" is here. The problem is to understand the operation of this complex economy in the light of frequently conflicting theories. It is proposed that a new approach be found, leading not perhaps to complete agreement, but at least to a meeting ground among the different schools. Through this new approach neomarginalists, and "structuralists," Keynesians and Marxists "could speak a common language." The result would be a reassuring economic understanding.

The author cautiously points out that his essay should be regarded more as a consideration of a current problem than a new theory; not as a general statement but only as a systematic preface to such a statement. The intention is to give a provisional synthesis of the scattered contributions in the different social sciences as applied to economics. The aim is to contribute to the solution of the present paradox in which the economist finds himself.

It is emphasized that economic thought is now discredited largely because of its incapacity to solve two closely linked problems: the choice between macroeconomics and microeconomics and that between a dynamic scheme of disequilibrium and a static scheme of equilibrium. Different schools view these problems from different angles. Their incapacity to solve these two

dilemmas seems to originate in their faulty analytical approach. It is stressed that their approach is too limited and implies too narrow a conception of economics. Instead, a broader conception is advocated. The central idea is to show that economic behavior and social structures are tied to each other; the mode and the nature of different kinds of relations, of production and distribution are determined accordingly; and under the effects of changing circumstances the bond of causality links altered behavior with structural modifications.

If this conception is accepted, then economics becomes a broad field of study. It becomes the analysis of dynamic social systems that the individuals, in groups, maintain as supports of the structures; they perpetuate these structures by their conscious behavior through actual relations in connection with activity which permits them to satisfy wants by the use of scarce resources; the creation of these resources necessitates a common labor implying differentiated and complementary roles. This conception seems to be favored by a number of contemporary economists in Europe, and especially in France, who question the nature and scope of economic science.

The integration in the theoretical analysis of the "extra-economic" elements (compulsion, consideration of social and political structures, investigation of total human behavior) is defended. The argument is that if the economist declines to take these elements into account he risks rendering his discipline radically dependent on other human sciences. In general, economic phenomena are visualized as only a part of total human phenomena. Hence the necessity for a broad approach.

Economic fluctuations are regarded as signs of tension and of structural transformation. Changing circumstances transform the situation of the groups in the system. They also change the significance of many things. Thus, a new situation appears as a challenge for the groups. To it they respond through invention, through material and immaterial means, and new models of action. The behavior of adaptation helps to actuate these structural changes because the reality of these structures is based on behavior. Thus, the combination of the models of operation of the economy and models of behavior provide foundations for the dynamics of the structures and of the systems explaining transformation and dynamic evolution.

Although the author raises more questions than he answers, on the whole he succeeds in bringing significant ideas into sharp focus. Thus he achieves his modest objective. He shows an interesting insight into many aspects of the problem. A unity of thought and high level of competency are to be found throughout.

No doubt few would agree with the author completely. Some would even say, in this country, that many of the ideas are outside the field of economics. Apparently, the approach arouses more interest in European countries than in the United States. It is too early to say whether a carefully worked-out theory would really lead to the expected result. However, it is safe to say that more attention to some of the stimulating ideas of Nicolai could increase our understanding of many of the problems we face in a rapidly changing world affecting behavior, structures and systems. Possibly, we could even make a

step forward toward a more satisfactory theory of economic development.

The method of the author is commendable. It is good to see that some economists, these days, have the courage to advocate a broader analytical approach.

**Price and Allocation Theory; Income and Employment Theory;
Related Empirical Studies; History of Economic Thought**

The Problem of Rising Prices. By WILLIAM FELLNER, MILTON GILBERT, BENT HANSEN, RICHARD KAHN, FRIEDRICH LUTZ, AND PIETER DE WOLFF. Washington: Organization for European Economic Co-operation, 1961. Pp. 75 and 488. \$3.75.

The first 75 pages of this book consists of a report by a committee of experts on inflation in the OEEC countries (including the United States) during the period 1953-59. The remaining 488 pages consists of country studies prepared by Wilfred Beckerman and Stephen Marris of the OEEC Secretariat.

Unfortunately detailed examination of the country studies is beyond the scope of this review and the competence of the reviewer. cursory perusal of them, however, indicates that they are a notable contribution to the economic history of the period, even though experts from the individual countries may question some points of detail. A great deal of information has been very succinctly provided.

The report is also remarkable, not so much for its originality, as for the fact that a group of economists whose political points of view are by no means identical have reached substantial agreement in an area that is highly charged with political emotion. Perhaps the degree of objectivity they have achieved is only to be expected among economists. But it is not often realized. The authors approach their problem straightforwardly, examining in succession the role of demand, the role of wages and the role of monopolistic pricing. Each section deals separately with both diagnosis and prescription.

The committee believes that excess, and not merely permissive demand was a major inflationary force during 1955-57. By this it is meant that shortages of capacity or labor in major segments of the economy contributed largely to the price increases that occurred. During this period some governments were impelled to take restrictive monetary and fiscal action not primarily to curb inflation but to protect their balances of payments. The committee concludes on the basis of this experience that fiscal and monetary measures are adequate to curb demand inflation in a reasonably short time.

Nevertheless they confess that they are far from unanimous, even in retrospect, concerning the restrictive action that should have been taken during the boom. They pin some of their hopes for the future on improved statistical information. They pin others on additional instruments of policy, particularly discretionary authority to change tax rates and to control consumer credit.

The real problems, however, may be political rather than economic. 1955

was a glorious year of peace and prosperity, not to be marred by monetary and fiscal spoil-sports whose actions might reduce profits or even increase unemployment. But that may be too cynical. The United States, at any rate learnt a lesson, and applied it with an overdose of deflation in 1960. However, it was the balance of payments rather than inflation that spurred the government to action.

The type of inflation with which the committee is mainly concerned, as a continuing problem, is the wage-price variety. While they agree that wage pressure on the price level has varied among countries, they conclude that it has been both "an important and an independent inflationary force" in the United Kingdom, the United States, the Netherlands, and the three Scandinavian countries of OEEC.

By an "independent force," the committee means that money wages under collective bargaining increase more rapidly than they would if wages were determined solely by the scarcity of labor in relation to employers' requirements. Since this point of view has been questioned, the committee presents a detailed and convincing empirical argument in support of its position. But theory seems to be enough to settle the matter. To take the extreme case, it is hard to see how agreements between monopolistic organizations of employers and employees can yield the same results as would a competitive labor market.

The committee agrees that demand influences wages directly, and also affects the course of collective bargaining. It might also have added that a permissive fiscal and monetary policy that does no more than validate the price and wage increases arrived at by collective bargaining can itself affect the future course of bargaining in an inflationary direction.

The authors, perhaps wisely, refrain from producing a theory of collective bargaining. They do not attempt an analysis of the factors that influence wage demands and employer resistance. They are content to point out that despite wide differences in institutions, ideology and bargaining practice, there can be and frequently are chronic tendencies for average wage increases to exceed average productivity increases.

With respect to remedies, the committee agrees that fiscal and monetary discipline is not an appropriate remedy for wage-price inflation. In this they may go too far. One can readily agree that prolonged unemployment is an economically inefficient and socially unacceptable remedy. But does that mean that the government must never allow output to decline and unemployment to increase as a result of inflationary wages and price increases? In its pursuit of a wages policy, should the government never issue a warning that an inflationary "wage round" will not be validated by an increase in the money supply? If it eschews the use of this weapon, its ability to control the situation may be greatly weakened.

Nevertheless the committee does reject fiscal and monetary action and is divided on what ought to be done. The majority advocates the adoption of national wage policies. By that they mean neither frantic intervention nor pallid exhortation, but proclamation of a wage norm which would carry such

moral force that the burden of justification would be thrown on those who departed from it. The idea has been in circulation for a long time, it has been widely discussed, and, as the report shows, governments have done very little about it. The main exception has been the Netherlands whose task has been the relatively easy one of so timing wage, and consequently price, increases so as to prevent the balance-of-payments surplus from growing too large. Whatever the difficulties of a wage policy for the economy as a whole, the majority is surely right in rebuking governments for permitting wage disorder in their public sectors.

The minority of the committee (Fellner and Lutz) are sceptical of general norms and believe that an effective wage policy would imply extensive regulation of individual wages and prices. Since this is an unappealing prospect, their conclusion is that "the desirable solution requires sufficiently modifying the size and the functions of the organizational units on both sides of the bargaining table." In other words, labor and management should bargain in smaller groups. This may be easier said than done. I am afraid one of the most baffling and complex problems of modern economic society remains unsolved.

The report next considers monopolistic pricing as an independent inflationary force. The committee agrees that autonomous efforts to increase profit margins can and do occur, but it argues that this is less serious than the wage push. Such efforts can provide the initial conditions for inflation, but do not produce the spiraling effect. In the committee's words "there can be a wage-price spiral but not a profit-price spiral." I am not sure that they are right from the analytic point of view. Efforts to increase the profits share of national income are likely to induce union efforts to restore the wages share at least to the old level. If business as a whole persists in trying to increase the profits share, it can produce a spiral that is very similar to that produced by labor efforts to increase the labor share. The authors are on firmer ground when they assert, as a matter of fact, that there are not "profits rounds" in the same sense as there are "wages rounds." The sanctions of competition may work better against profit-induced inflation than against wage pressures.

The remedy proposed is to strengthen the forces of competition, including foreign competition. The report also notes the possibility of consultation between government and business concerning prices, but it also notes that, while such consultation may avert price increase, it may also increase the reluctance of business to reduce prices.

Finally, and very briefly, the report considers the relation of internal price stability to international balance. It concludes that stability, while not ideal, is definitely preferable to general inflation among countries. The reason is that inflation, if it is allowed to occur, proceeds at different rates in different countries, and produces price discrepancies that have no relation to the requirements of international balance, and hence tend to disrupt it. A general regime of stable prices may also be inconsistent with international balance with fixed exchange rates. But such inconsistencies are likely to be less than those that would occur under general inflation. The committee might also

have added that if a country has the ability to achieve price stability, it is also likely to be able to achieve a controlled price increase, as was done in the Netherlands.

As an afterthought, the committee states that price stability will contribute to economic growth and, provided growth targets are not "unrealistic," growth will contribute to price stability.

One striking feature of the report is that a representative group of economists regards it as a self-evident truth that price stability should be a major objective of policy, and here they reflect a general trend in economic thinking. The case against moderate inflation is not easy to make on purely economic grounds. It probably rests on a growing conviction that a stable society cannot be based on a money illusion.

ARTHUR SMITHIES

Harvard University

Proceedings of the Conference on Consumption and Saving. Vols. I and II. Edited by IRWIN FRIEND AND ROBERT JONES. Philadelphia: Wharton School of Finance and Commerce, University of Pennsylvania, 1960. Pp. xxiv, 480; ii, 498.

These two volumes relate to the proceedings of a conference held in the spring of 1959 on the analysis of family budgets, specifically the Bureau of Labor Statistics' survey for 1950-51. The first volume is mainly concerned with the demand for individual groups of commodities, food, clothing, housing, automobiles and so on; the second with the consumption or saving function. The organizers of the conference appear to have aimed at a fairly complete coverage by commodity groups but to have left contributors to develop their analyses as they thought best without trying to get prior agreement on concepts and methods which would have led to a more fully integrated and easily comparable set of results. Despite the staggering amount of numerical calculations, many of the papers seem in the nature of progress reports, being much longer and less incisive than one would expect in a finished product. The authors vary in the extent to which they provide their papers with a beginning and an end and, although there are plenty of comments, there is very little in the way of a general appraisal either of the state of demand analysis in general or of the specific contribution of this collection of papers. The reader may well find it difficult to discover what is new in all this and to distinguish steps forward from steps backward. Accordingly, I shall try my hand at a summing up.

In the first place most of the papers represent an attempt to analyze a very voluminous but at the same time very limited set of observations and make use of modern high-speed computing equipment in doing so. This means that something can be attempted which has rarely been attempted before on a large scale, namely the detailed and simultaneous analysis of family responses to a large number of economic, demographic and environmental factors. In the past it has usually been necessary to pursue a policy of divide and conquer: assuming away the niceties of unit-consumer scales when studying the form of the Engel curve, assuming away economies of scale when study-

ing unit-consumer scales and so on. But in all these partial studies quite a lot has been learnt about which forms of relationship are likely to succeed and which are not, and this does not seem to me to be as fully reflected in the present volumes as I should have expected.

For example, considerable stress is laid on linearity and additivity. Linearity is all very well as a first approximation especially in situations where the range of variability is limited. Additivity may be necessary in general economic models where accounting constraints have to be met. But they seem to me out of place in the analysis of family budgets where the range of variation is enormous and the object is to get as close as possible to the underlying structure. Allen and Bowley could reasonably adopt linear Engel curves in their study of 1935 but they seem decidedly old hat nowadays.

Linear Engel curves carry the implication that all elasticities tend to one and log-linear Engel curves carry the implication that all elasticities are constants. We do not believe that Engel curves have these properties, so why continue to pretend they have? Perhaps the answer is that my computer does not like logistics or log-normal integrals; it likes polynomials. But the answer to that is, go away and teach your computer something useful.

It is true that by holding enough things constant, everything can be reduced to linearity. At the same time, however, we shall reduce everything to near-uniqueness and the generalizations of science will come to a full stop. For example in a paper on the demand for food, a number of log-linear regressions are carried out for different categories of race and region. It is found that whites and northern Negroes have an income elasticity of demand around one-half as against about two-thirds for southern Negroes. This is just what one would expect since southern Negroes are relatively poor. In other words the difference is probably not due to racial or regional differences but appears as a consequence of an inappropriate form of Engel curve.

In the second place, a number of techniques are represented in these volumes which seem to me very useful in exploring consumers' behavior. One of these is the analysis of variance and covariance as exemplified by the papers of Lippitt and Peters on furniture and furnishings. The point about these methods is that they enable us to get some idea of relationships in areas where we have little guidance from theory or past experience without imposing a particular form a priori. Another example is the use of two cross-section studies combined with regression and covariance methods. Houthakker and Haldi study household investment in automobiles in this way, concentrating on three determining factors: income, initial stock, and personal tastes. A third example is the development of the idea of a certain equilibrium or balance among the various items in the capital account which is taken as the basis for an interesting study of assets and claims by Watts and Tobin. They show that households tend to maintain some sort of balance in their capital accounts and that adjustments tend to eliminate rather than perpetuate deviations from the preferred portfolio pattern.

In the third place, in the discussion of saving there are signs of a tendency to accept a treatment of saving which would include the finance of net investment in consumers' durables, consumption of these goods being restricted

to the value of their depreciation. Thus Friend and Jones show that an extra \$1 on durables is associated with a diminution of 80 cents in saving. I hope this tendency persists and eventually brings about a change in national accounting practice. It takes a very ham-handed family to consume a car, washing machine or radio in the year in which it is bought, and a national balance sheet which includes business cars but not private cars is something of an oddity. For analytical purposes it seems to me that one needs two concepts: saving, the excess of disposable income over consumption; and net lending, the excess of disposable incomings, current or capital, over the absorption of commodities on either current or capital account.

Finally, Friedman's permanent income hypothesis runs as an undercurrent in many of the papers and is treated explicitly in several. It comes in for some pretty rough treatment at the hands of Bodkin in an interesting paper on windfall income and consumption. To me the hypothesis is just one of many ways of trying to account for the difference between long- and short-term responses to measured income. I hope it is not going to become a test of orthodoxy and so a great inhibitor as that other good idea, simultaneous equations estimation, was a few years ago.

To sum up, these volumes mirror the energetic attempts now being made to grapple with the detailed problems of consumers' behavior. Although the contributors are all perfectly familiar with the state of play they seem to me to show remarkably little sense of what we know and what we do not know, to build less than I should expect on the existing body of knowledge, and to put immense faith in modern computing techniques. What we want is not just another batch of coefficients but a gradual extension and refinement of knowledge, revolutionized in some aspect from time to time when a really good new idea comes along.

RICHARD STONE

Cambridge, England

Investment and Production: A Study in the Theory of the Capital-Using Enterprise. By VERNON L. SMITH. Cambridge: Harvard University Press, 1961. Pp. xi, 340. \$7.50.

From current textbooks, the student is likely to conclude that the traditional topics of production and investment in the theory of the firm are a quiet backwater, of no current theoretical interest or practical relevance. Vernon Smith's fine volume demonstrates that this conclusion is erroneous on both points. Quite apart from the recent burgeoning of linear programming and operations research, Smith shows that the classical theory of the firm is analytically exciting and of the highest relevance for actual production processes.

There is too much material in this closely-packed book for detailed summary, so I shall concentrate upon a discussion of some of the central themes unifying Smith's analysis. The most fundamental theme is Smith's attempt to provide an integrated solution for the theories of investment and production. Smith's basic, simplest production function is of the form $y = f(x_1, X_2)$, where y is flow of current output, x_1 is flow of current input, and X_2 is the

stock of durable or capital input. In this model, the basic production decision involves (for any given output) an optimal balance between x_1 and X_2 —hence, it is inseparable from the investment decision of how much of the durable input, X_2 , to acquire. Curiously, Smith is never very explicit about the assumptions underlying his basic contention here. It is certainly true, for the economy as a whole, that capital goods must be acquired by investment—but Smith's analysis is entirely on the level of the firm. Clearly, if there is a rental market, any given firm could hire the services of capital goods with no investment requirement—this would still be substantially true if there were an effective resale market for used capital goods. Nevertheless, since in point of fact such markets frequently do not exist, Smith's analysis is relevant and useful for a range of important situations.

Smith's second theme—irreversibility of production and cost functions—stems from the assumed unavailability of rental or resale markets for the durable input. His typical cost function has a declining long-run marginal curve LMC, showing increasing returns as the capital good is—hypothetically—varied over a continuum of possible scales. Once a particular scale has been selected, in Smith's analysis the "virtual" LMC curve is no longer relevant; with the given durable input, the firm is constrained to operate along a short-run curve, SMC. Now, assuming a rise in demand, there are three modes of achieving larger output: (1) for small changes, movement along SMC is optimal, (2) for intermediate changes, it is best to install a second facility parallel to the first, and (3) for very large changes, the falling LMC curve may justify discarding the original facility and investing in a much larger new one. With this basic model, Smith develops output supply functions and input demand functions for firm and industry—all being importantly influenced by the irreversibility of the underlying production function.

Another general theme—one of the most exciting aspects of the book—is Smith's attempt to relate the traditional production function to actual conditions of production. He provides many illustrations of "engineering economy" solutions to production problems, starting with Lord Kelvin's 1881 paper balancing the value of energy lost in heat against initial investment to find the optimal diameter of electrical conducting cable. Despite the brilliant individual successes of engineering economy, it is clear that traditional economics has much to offer engineers in the way of a formalized discipline of solution. But conversely, economics has much to learn as well. Smith shows that there are certain generalized classes of processes involving characteristic problems—e.g., economic balance in energy or mass transfers, optimal batch size in discrete batch production, and multiple-pass selection in regenerative processes. Furthermore, processes may be linked in series or parallel in making up the over-all production function. Smith shows how all these problems can be elegantly analyzed by appropriate use of the apparatus of economic theory.

Unfortunately, Smith's book is weaker on the investment than on the production side—in my opinion, for lack of a strong foundation in the theory of economic decision over time (as developed in classical form by Irving

Fisher). Smith tends to solve each problem with an explicit or implicit "criterion" formula, generally justified by some more or less *ad hoc* argument. This leads to vagueness or circularity when, for example, a "current profit" criterion is being employed and the question arises of "allocating" the capital cost of the durable instrument over time. For the cases Smith discusses, all that is involved is annualizing a present sum into a level flow—therefore, the respectful attention paid to certain accounting conventions about "depreciation" seems unwarranted. Oddly enough, in some cases where Smith uses a present-value criterion, he discounts back to the present the current-cost figure obtained by annualizing what was a present outlay to begin with—taking the long way around. In this connection, at one point there seems to be a definite error. In discussing "capital rationing," Smith employs a "discounted current annual profit" criterion, discounting all profits back to the present at the market rate of interest. However, the essence of capital-rationing situations is that, since borrowing ability is arbitrarily rationed, the market rate of interest is not an economically relevant alternative—some other form of analysis, such as a shadow-price marginal equivalence between current and future funds, is required to obtain the correct solution.

However, these are minor defects in a really fine contribution, the scope of which may be suggested by the following partial list of problems to which analytical solutions are provided by Smith: production and investment with indestructible capital goods; with capital goods of limited life, involving the problems of age-distribution and of optimal replacement; with capital goods that become obsolescent over time, and that decline in efficiency with cumulative use; with multistage and multifacility productive processes; and with level or fluctuating output patterns. The book is not, in general, easy reading—but it is a real advance in economic theory, essential for anyone concerned with the economics of the firm.

Theory and Application of Interindustry Analysis. By ISAMU YAMADA.
Tokyo: Kinokuniya Bookstore Co. for Institute of Economic Research,
Hitotsubashi University, 1961. Pp. 254.

As the title suggests, Professor Yamada devotes himself first to the treatment of input-output theory and then to applications of that theory in the context of the postwar Japanese economy. Given the pace of advance in interindustry analysis in recent years and the paucity of general works of the Chenery-Clark variety, the present volume, again judging by its title, augured to help fill a rather important professional need. Yamada, however, makes it abundantly clear that he is not engaged in writing an advanced text but is mainly intent on airing his own original contributions to the theory of input-output analysis. Proceeding in this vein, he makes no attempt at comprehensiveness—paying no attention for instance to the various dynamic models—and concentrates on those facets to which he hopes to make a spe-

cific contribution. The theoretical section of his book at least must thus be judged largely on the merit of these contributions.

We may partition progress in the theory of interindustry analysis roughly into advances in the so-called behavioristic and technical branches. The behavioristic theory extends the original Leontief model by introducing superior behavioristic assumptions; i.e., the introduction of each new space or time dimension has always been accomplished in this fashion. The technical theory, on the other hand, applies more to the realm of statistical estimation, the solution of the aggregation problem and comparative static prediction. In the theoretical portion (Part I) of the present volume, Chapters 1, 4 and 5 may be said to be concerned with advancing Yamada's contributions to the behavioristic theory, and Chapters 2 and 3, with the more technical side of interindustry analysis. Quite appropriately the author seems to be more concerned with the former, in which the economist qua economist should be in a position to make a maximum contribution to the advancement of knowledge.

Yamada's major original suggestion on this score is contained in his attempt (Ch. 5) to partially "close" the system by treating the consumption component of final demand as an endogenous variable. The introduction of a new behavioristic assumption in the form of a consumption function is of major importance in evaluating the economic significance of Yamada's contribution. Unfortunately, however, the function he has chosen seems to be more the fortuitous result of his mathematical manipulations than in correspondence with, at least this reviewer's, economic intuition. Consumption is viewed as a fixed fraction of the export surplus, i.e., exports minus imports, of a *particular* commodity; one might well question the validity of any theory built on such an assumption—even when the factor of proportionality is called a propensity to consume and asserted to be of pure Keynesian stock (p. 79).

Elsewhere in the theoretical sections as well, one has the uncomfortable feeling that Yamada may have let himself be guided somewhat more than is prudent by mathematical symbols rather than economic reasoning. In Chapter 1, for example, he sets out to solve not only the traditional allocation problem and its dual, relating to relative prices, but also—and simultaneously—the problems of employment and of the absolute level of prices. As is well known, traditional input-output theory permits us to determine relative output ratios in the real system and relative prices in the dual system—but Yamada further promises the determination of the level of employment in the former and of the price level in the latter. A theory of employment and of inflation built into the model at the relatively low cost of adding two equations (his consumption function and his supply function) would indeed constitute quite a remarkable achievement. Unfortunately, however, en route one has to accept a consumption function which is quite independent of national income and a theory of price-level determination which makes use of neither the quantity theory, nor liquidity preference nor institutional factors in factor or product markets. With key behavioristic assumptions strikingly unconvincing, one is forced to conclude that his system is fully determined only in the mathematical sense.

Even more difficult to digest is the fact that primary factor costs seem to be endogenously determined in Yamada's model. In traditional input-output theory such costs are given (as labor coefficients) and reflect a particular state of technology. Yamada's model, on the other hand, seems to indicate that primary factor costs fluctuate as the demand for goods fluctuates; in other words a change in consumer preference leads to a change in technology!

With respect to the technological theory of interindustry analysis, Yamada's aims are somewhat more modest and his results consequently less controversial. Chapter 2 for example, contains a conventional and correct discussion of the aggregation problem, and Chapter 3, an unconventional discussion concerned with "the interchange between an endogenous sector and an exogenous sector," also correct, but little more than a rather trivial contribution to computation procedures.

The bulk of Part II concerned with interindustry applications is devoted to fitting Japanese input-output data, compiled by the Japanese Planning Agency and the Ministry of International Trade and Industry for the years 1951, 1953, and 1955, into so-called Euler graphs or balanced tables. By demonstrating the "rightness" of his equations via the derivation of balanced square tables from input-output data, Yamada seems to expect somehow to validate his prior theoretical approach. But it is difficult to find much beyond the neat processing of data in these relatively descriptive sections—no analytical observations, for example, about the "economic circulatory" structure of the economy, and no attempt to achieve a linkage with the behavioristic data postulated earlier. When innovations are advanced, as with the introduction of "distribution coefficients" (measuring the portion of total output allocated for various uses) their significance is not demonstrated. This reviewer once again had the feeling that mathematical symmetry rather than economic logic prompted the similarity of treatment accorded to these (unstable) "distribution coefficients" and the (stable) cost coefficients.

Yamada's final chapter on economic planning starts promisingly enough by introducing a conceptual framework involving "predictable variables," i.e., exogenous and reasonably predictable on extra-model grounds; "planning variables," i.e., instrument variables controlled by planning authorities; and "endogenous variables." However, this machinery is never utilized but is followed by observations of a largely unrelated character. One cannot escape the impression once again that Yamada's considerable talents for presenting, in terse straight-forward fashion, a tightly-knit mathematical framework have not been put to optimal use.

GUSTAV RANIS

Yale University

Ciclo economico e politica anti-ciclica. By VITTORIO MARRAMA. Naples: Giannini Publishers, 1961. Pp. 386.

This lucid and attractive survey of modern business cycle theory and policies, based on courses offered by the author in the University of Naples, Italy, can be commended as a model of classroom technique. The material

is well organized, its various parts are held together by a clearly recognizable thread, and its implied emphasis is on the way in which different theories complement each other, rather than on controversy. The level of the discussion is analytical, yet accessible to the nonmathematical reader, and is happily blended with factual references and statistical illustrations.

After a few introductory chapters, which furnish also a framework for the entire treatment, the narrative proceeds with its main task—a presentation and critical review of the major doctrines at the center of the contemporary stage. By natural and largely chronological steps, it unfolds the cobweb theorem, some of the findings of the National Bureau economists, the inventory cycle, a number of basic econometric models, and, in particular, the essentials of *The General Theory* and of later theories which make use of the multiplier, of the accelerator or of a combination of the two. A later group of chapters deals with economic policies, and discusses the potentialities and limitations of built-in stabilizers and of what Marrama calls “discretionary stabilizers,” such as income redistribution, the management of interest rates and compensatory financing. This is followed by an examination of the conditions for equilibrium at full employment, and related problems of excess-demand and wage-push inflationary pressures, and by a review of international stabilization methods, such as buffer stocks, commodity agreements, International Monetary Fund policies, and so forth. The concluding chapters revert to the consideration of theoretical models, in particular those which combine cyclical with long-term trend determinants.

An important feature of the author's treatment is the introduction of a diagrammatic presentation, in the form of a flow chart, depicting the mutual dependence and interaction of the main flows of the national economic accounts. There is a major flow, of rectangular shape, the left side of which represents the GNP while its right side reflects the sum of its component parts: consumer expenditure plus gross investment plus the foreign balance = total expenditure = GNP. In turn total expenditure is linked, both ways (that is, in and out) to three subsidiary flows, reflecting the behavior of the government account (revenue and expenditure), of the private capital account (gross saving and investment) and of the foreign payments account. Furthermore, the government account and the private capital account are linked both ways to the flow of credit made available by the banking system, and the foreign payments account to the flow of outside financial facilities available to the domestic system.

One of the main purposes of the chart is to emphasize the role of private capital investment on the general level of economic activity, and to underline Marrama's conclusion that the rate of net private investment is the main determinant of the business cycle. But this particular interpretation stems in fact from certain drastically simplified assumptions which have nothing to do with the chart, that is that all other determinants are likely to be constant. Consumer demand is assumed to be a stable function of the pattern of income distribution, the charges for maintenance and amortization are held to be unchanged from year to year, monetary policy is assumed to be of the neutral type and the government budget is supposed to be in balance. These assump-

tions are of course open to challenge, but since they are clearly stated the reader has been warned, and can draw his own inferences as to their plausibility.

Another significant section of the book deals with the international propagation of the business cycle. It makes use of the multiplier, the J. J. Polak's "international reflection ratio," but mainly of an approach developed a few years ago by Marrama, focusing upon the degree to which "peripheral" areas of the international economy, either industrialized or producers of primary materials and commodities, are dependent on trade among themselves and in particular on trade with the United States, which is viewed as the center of the world economy. By combining various criteria, such as the ratio of exports to national income, the income elasticity of the demand for exports and the export structure by major commodities and destination, one can assign to each "peripheral" country a numerical coefficient, reflecting its vulnerability to changes originating from the outside, and in particular from "the center." The results are of interest, though of late the structure of the world economy has become increasingly bi-polar, owing to the renewed strength of Western Europe and Japan.

From his vantage point, the author calls attention, by way of statistical illustrations, to interesting features of the contemporary evolution of the Italian economy, including the building cycle, short-term postwar waves of expansion and correction, changes in consumer demand brought about by the income effect which is operative in an expanding economy, and structural changes in the balance of payments. Of equal interest are references to the role of Marco Fanno as one of the architects of the acceleration theory, and to the contribution made to business cycle literature by other contemporary Italian scholars, such as di Fenizio, Demaria, Papi and Vito, as well as by younger economists such as Brambilla, Graziani, Jr., Mazzocchi, Talamona and others. The author's own contributions, traceable in part to earlier work, are hidden in the running commentary in a refreshingly unobtrusive fashion.

BRUNO FOA

New York, N.Y.

Il profitto nella teoria economica contemporanea. By FRANCESCA DUCHINI.
Milan: A. Giuffrè, 1960. Pp. 236. L. 1.200.

It is a minor oddity that profit, the Golden Fleece of most economic ventures in Western industrial society, remains withal a term with no unique meaning. Neither its size nor causes nor consequences can be clearly discerned, let alone measured. On one showing it is the result of economic progress, but on another it is its mainspring. One respectable opinion has it that profit arises mainly from the happenstance of events in a planless society; per contra it is depicted by others as a rough measure of planned scarcity, an index of the subordination of public benefit to private advantage. It is begotten by waiting, or it comes from plunging ahead. In the instrumental sense it is entirely subjective, and yet it is closely computed and then taxed.

Of hypotheses, models, and conjectures concerning profit there is truly no dearth, and this helpful book affords synopses of a great number of them.

Mainly, signorina Duchini's intention was to sketch developments in, or perhaps more accurately, ramifications of, various profit theories from about the close of what Schumpeter called the "classical period," circa 1914, to the present. At the outset, however, she has compressed into less than a hundred pages practically the whole of earlier profit theory from the times of the founding fathers of economic science. This part of the book will prove highly valuable to people interested in the history of economic ideas, for no such compendium of profit theory has been published, to my knowledge, in this century. One is reminded in a way of *Capital and Interest* although Böhm-Bawerk's masterly criticisms of earlier exponents of his chosen subject are not paralleled in the present work, which is for the most part strictly expository.

The author then surveys a large number of fairly recent and variously noteworthy writings relating to profit that have appeared during and subsequent to the interwar years. It turns out that they have nearly all been in some sense macroeconomic; not much time is spent any more in bootless speculations concerning either the ethical or psychological aspects of profit. The author well says (pp. 226-27) that these are matters best referred to other disciplines.

The book makes special note of theories wherein profit is a strategic factor in economic growth. For obvious reasons Schumpeter is awarded a prominent place; indeed, it is the author's estimate that most (but not all) modern models are derivative in some degree from the work of either Schumpeter or Knight. The contributions of Kaldor, Kalecki, Duesenberry, and other European and U.S. writers too numerous to mention here have been sifted for common elements, of which there are, apparently, few enough. At any rate signorina Duchini has not felt justified in hazarding a guess as to the direction being taken by profit theory. While it is clear enough that contemporary writers agree that profit is endo-originating, exclusively dynamic in origin, and merely one of a number of mutually dependent phenomena, there is little uniformity of opinion beyond this, and no one line of inquiry now seems more promising than any other. The root reason for this is the opacity of the term itself.

The book manifests solid scholarship and good planning. The index is very thorough. In English the book would be a minor boon.

A. STUART HALL

University of Nebraska

Ekonomicheskie zakony sotsializma i ikh ispol'zovanie. (Economic Laws of Socialism and their Utilization.) Edited by I. A. ERMAKOV. Moscow: Sotsekgiz, 1960. Pp. 426.

Among the more dubious elements of Stalin's doctrinal legacy must surely be counted the "objective economic laws of socialism." First imposed by the dictator on Soviet economics in early 1941, they formed the central theme of his well-known last theoretical work, *Economic Problems of Socialism in the USSR* (1952), and, unlike some other parts of his doctrinal edifice, were retained bodily and even somewhat elaborated in the years following his

death. Loosely constructed, ambiguously formulated, vaguely delimited, and declaratively posited, they have been a heavy drag on the development of Soviet economics in the post-Stalin period, and especially on the recent attempts to channel it toward a more operational and rational discipline. On the other hand, they have given ample excuse for the sort of wordy, monotonous, repetitive, and vacuous regurgitation that perennially fills thousands of pages in Soviet economic journals and books and is all too familiar to their readers.

Altogether some eight "economic laws of socialism" have come to light; e.g., the "law of planful, proportional development," the "law of steady growth of labor productivity," the "law of socialist accumulation," and the "law of preferential growth of the means of production." (Concerning the last, see the trenchant criticism of Alexander Gerschenkron, this *Review*, September 1959, pp. 734-37). Stalin called them "objective" because he saw them operating outside the will of man—in this regard he distinguished them from juridical laws—and asserted that a socialist society (i.e., the Soviet) must take them into account for policy and planning and can violate them only at its peril. We may surmise that he had a double purpose in enunciating the concept of objective law: to restrain the more impatient of the builders of socialism, and at the same time to legitimize his own policies in the eyes of the faithful.

In point of fact both the adjective "objective" and the contrast with juridical laws are questionable. With the special exception of the "law of value," on which more in a moment, the "laws" are not statistical or historical generalizations, whether empirical or hypothetical. Rather, they are—not unlike juridical laws—prescriptive, imperative, and enjoining, with a large dose of the admonitory and educative thrown in. They represent certain desiderata and goals (high rate of growth, rising standards of living) and certain means to their attainment (planning, balanced development, material incentives, high rate of investment). As such they are anything but divorced from the will of man, or, at any rate, from the will of the Man on Top. If they express "necessities"—which is what economic laws represent in the usual Soviet conception—then they are the necessities stemming from a certain definite (and quite subjective) set of values and preferences. Lastly, as operational guides to the planners they are worthless.

The "law of value," one of the eight, is in a somewhat different category because it is at least Marx's own creation, and was meant by him to be a social law in the usual sense of an empirical generalization. Although even in its own day not the last word in value theory, it sought to represent the regularities of price formation in a capitalist market economy under certain restrictive assumptions (pure competition, constant costs, etc.). Its revival in the Soviet context, where capitalism and the market mechanism have been deliberately abolished and prices are decreed, raises many difficult questions. And indeed, its normative application (but not its applicability!) under Soviet conditions has been the subject of a very lively and extensive debate among Soviet economists in the past six years.

The book under review is, in most respects, a rather routine contribution

to the on-going Soviet bibliography on the "economic laws of socialism." Apart from the editor's introduction, there are thirteen contributions. Each is devoted to a single "law," though several "laws" rate more than one essay. The contributors are generally little known to western sovietologists. The volume, sponsored by the Social Science Administration of the Ministry of Higher Education, seems to be intended for student use. The preface suggests that the book may fill a certain gap in the Soviet literature. In so far as theory is concerned, this is rather doubtful, since it offers little beyond what can be found in the official and (in post-Stalin terms) orthodox *Textbook of Political Economy* (successive Russian editions since 1954; also translations into major foreign languages). The philosophically and epistemologically orthodox tone of Ermakov's book is set in the first paragraph of the Introduction (p. 3, my italics): "Penetration into the *essence (sushchnost')* of economic phenomena and processes amounts to cognition of the economic laws of development of social production." It is, among other things, the search for the *essence* of economic value and economic laws, rather than their use and utility, that has led Soviet economics into its blind alley and has kept it there largely until now.

Nonetheless the specialists will not find the volume entirely devoid of interest. Some of the less theoretical contributions are quite informative, factually and analytically. Thus, Ofmanis ("The Law of Value and Business-like Management [*Khozraschet*]," pp. 218-49) gives a good deal of data on widely varying rates of profit and loss among Latvian enterprises and on what happens under such conditions. Khudokormov ("The Utilization of Economic Laws in the Marketing of Kolkhoz Output," pp. 281-319) does a similar job with regard to collective farms. Kapustin ("The Economic Law of Distribution According to Labor . . .," pp. 320-57) summarizes the current wage reform. Finally, Osad'ko ("Distribution According to Labor in Kolkhozy . . .," pp. 358-93) is also informative, and incidentally shows in effect that much of this distribution has *hardly* been "according to labor."

GREGORY GROSSMAN

University of California, Berkeley

Bestimmungsgründe des persönlichen Sparens—Ein Beitrag zur ökonomischen Verhaltensforschung. By WERNER PASCHKE. Berlin: Duncker and Humblot, 1961. Pp. 223. DM 28.60.

After a 25-page history of doctrine on savings, the author sets out to do four distinct things. First, he offers a sociological investigation of savings motivation. Riesman's three society types, the tradition-directed, the inner-directed, and the other-directed society types, are applied to the saver in a rather convincing way. Veblen, Duesenberry, and Modigliani-Brumberg are also reported on, and the author seems impressed (p. 46) by the extent to which quantitative economic theory, sociology, and psychology mutually influence one another in the United States!

Second, traditional economic theory of optimization by the household is summarized. In his attempt to apply Hicksian indifference analysis to the case of consumption (plotted horizontally) versus saving (plotted vertically),

the author manhandles the indifference map badly by saying that the locus of all tangency points with shifting budget lines "corresponds" to the 45° line used in Keynesian diagrams of the consumption function! Fisher's ingenious graphical technique (*The Theory of Interest*, Ch. 10, 11), specifically designed for the author's problem, is overlooked. In his criticism of the neo-classical theory of the household, the author reveals several misunderstandings: He misses the distinction between cardinal and ordinal utility, and categorically rejects the idea that the consumer is a consumer *only*, thus overlooking the ease with which Walras, for example, simultaneously determined an individual's demand for consumers' goods and his supply of productive services. Walras simply made the individual's utility a function of the quantities of consumers' goods purchased *and* of the quantities of productive services retained for his own use as leisure, garden plot, etc.

Third, the author makes his own suggestion, i.e. to adopt a radically new approach to the theory of saving. The household always faces a conflict between itself as a saver and itself as a consumer. This conflict is best seen, understood, and resolved, the author insists, as a zero-sum, two-person game in which the saver plays against the consumer. Zero-sum, the author explains on p. 115n., because a given income is assumed. Hence a "gain" for consumption is *eo ipso* a "loss" for saving. (This assumption throws us right back into the bad company of those neoclassicists, so severely borne down upon, who thought of the consumer as a consumer *only*, or is the reviewer mistaken?) Later, the two-person game is replaced by a three-person game with the saver, the hoarder, and the consumer as players, even forming coalitions. Some fancy game-theoretical nomenclature is reproduced here but never used really to specify, let alone solve, just one such split-personality game. If Paschke's suggestion to use the theory of games in the theory of savings is a fruitful one, he has yet to show it.

Fourth, the author turns to statistical observations. "Savings" here is measured as gross deposits in savings banks (*Sparkassen*), a rather arbitrary measure, and the author confines himself to an examination of the rate of interest-savings relationship and the income-savings relationship. Lack of data prevents testing of other relationships. No regressions are used, merely time charts and budget studies.*

HANS BREMS

University of Illinois

*The reader of the present review may be interested in alternative German work on the same subject and is referred to Gerhard Gehrig, *Bestimmungsfaktoren des Konsums in der Bundesrepublik* (Berlin and Munich: Duncker and Humblot, 1958). As for corporate saving, no part of the subject of the present work, the reader is referred to Walther G. Hoffmann, "Die unverteilten Gewinne der Kapitalgesellschaften in Deutschland 1871-1957," *Zeitschrift für die gesamte Staatswissenschaft* 1959, 115 (2), 271-91.

De prijsvorming van consumptiegoederen op oligopolistische markten. By A. HEERTJE. *Capita Selecta der Economie XXII*. Leiden: H. E. Stenfert Kroese N.V., 1960. Pp. viii, 111. f 12.

The main purpose of this concise book is to develop an integrated theoretical model of the process of price formation in the case of consumption goods,

assuming imperfect competition on the supply side and perfect competition on the demand side.

The originality of the approach lies in the successful integration which appears to have been achieved by Heertje between the theory of consumer behavior and the theory of imperfect competition. The behavior of firms, acting mainly as price and quantity adjusters, is analyzed for both oligopolistic and monopolistic conditions. One of the real merits of this work is that the theoretical model itself is formulated in such a way that it could be tested empirically and conceivably be given operational significance.

The first chapter is devoted to the formal and rigorous presentation of the theory of consumer behavior. The collective demand curve for any given good is derived through an aggregation process from the individual demand curves on the usual assumptions that the preference scales of the individual consumers are given in terms of ordinal utility functions and are mutually independent. The collective demand for any given commodity is expressed on a per-consumer basis and is shown to be a linear function of real per capita income and all relative prices.

In Chapter 2 the model is formally developed. The first step consists of trying to relate the producer's sales function (the firm's demand curve) to the collective demand curve for the same good. Whereas the collective demand curve depends on all relative prices, the firm in its sales function will only react to a limited number of price relationships. More specifically the entrepreneur under imperfect competition is said to react only to changes in the prices of the commodities which compete directly with his own output. These are the strategic prices as opposed to the prices of all other goods—the nonstrategic prices—which may affect the demand curve faced by the firm but which are ignored in the firm's decision-making process. From the standpoint of a firm producing good i , the quantity sold is a function of all strategic prices—including of course, the price of i —the level of real income, and a term reflecting the influence of the nonstrategic prices (which are assumed constant).

A reciprocal relationship is assumed to exist as between strategic prices, i.e., if the price of B's product is strategic to A, then the price of A's product is also strategic to B. The firm's demand function thus includes, as independent variables, elements representing both the presence of competing suppliers, through the coefficients of the strategic prices, and the strength of aggregate consumer demand, which is reflected by the constant term indicating the impact of the nonstrategic prices and real income. A market is defined as the cluster of firms which contains the same set of strategic prices; and price formation in this market can be explained in terms of the n sales functions which contain as explicit variables the n strategic prices. Each market is, as it were, a partial equilibrium model which is, however, related to the general equilibrium model through the nonstrategic prices appearing as an implicit variable in each sales function, and through real income.

A formal (mathematical) treatment of the behavior of the firm as a price and quantity adjuster and of the equilibrium conditions in each market completes Chapter 2.

The third chapter is devoted to monopoly theory. A monopoly is defined

as a market structure in which the sales function of the firm contains only one strategic price—the firm's own price—all other prices being considered nonstrategic. Advertisement can be used by the monopolist to affect the coefficient relating his total sales to real income; it can thus lead to a shift of his sales curve.

The final chapter dealing with oligopoly theory contains, together with Chapter 2, the crux of Heertje's contribution. Oligopoly is considered to be the most important market structure and is taken as the general case. Monopoly and pure competition are shown to be in fact special cases of oligopoly. An oligopoly is formed by the set of suppliers which take either the price or quantity variations of one another as strategic action parameters. Since reciprocity is assumed, the market structure can be fully identified in theory. The main difficulty in the treatment of oligopoly is in expressing the form which the reaction of suppliers will take in response to the action of one of them. Heertje assumes that the oligopolist's reaction function is predetermined by the underlying power structure which prevails in the market. The power structure itself depends on a number of factors—many of which are more psychological than economic in nature. Heertje assumes that each firm in the oligopoly strives to obtain a certain share of the market's total profits depending on its power position. Given this share, the author makes use of game theory to show the strategy (price) which will maximize the total profits of this individual firm. In so doing, Heertje rejects Fellner's assumption that oligopolists behave in such a way as to maximize profits for the industry as a whole and Baumol's more recent assumption that oligopolists strive to maximize total sales subject to a minimum profit margin. With the help of an oligopoly example giving the pay-off matrices for each supplier—assuming a nonzero sum game—Heertje derives the reaction function which will maximize the firm's profits.

In this model as in any other model of imperfect competition determinacy is only achieved when a number of essentially *a priori* behavioral assumptions are made.

The validity and realism of the following assumptions can be debated: (1) unitary income elasticity of demand (straight-line Engel curves) and more generally linearity assumptions throughout the model; (2) the reciprocal nature of strategic prices, and (3) the exclusion (noninclusion) of non-price variations as explicit action parameters of the firm (the impact of advertisement is discussed briefly but does not enter as an explicit variable in the sales function).

This work is an important contribution to oligopoly theory. Not only does it provide a concise synthesis of the Anglo-Saxon and continental European literature (particularly the Dutch literature) but, more important, it provides an internally consistent and elegant model within which the price formation of consumption goods can be explained under oligopolistic conditions. This book deserves a much wider audience than the necessarily limited set of readers at home with the Dutch language. Translation might be recommended.

ERIK THORBECKE

Iowa State University, Ames

The Workability of Input-Output Analysis. By MICHIO HATANAKA. Ludwigshafen am Rhein: Fachverlag für Wirtschaftstheorie und Ökonometrie, 1960. Pp. xxii, 310.

This is an able and imaginative econometric study, and a worthwhile addition to input-output literature. It is devoted largely to testing the static open input-output model, with production coefficients derived from an aggregated version of the 1947 U.S. table prepared by the Bureau of Labor Statistics. But there is such scrupulous consideration of the design of the tests and of the interpretation of results that the author's extensive discussion of these matters alone will reward readers with an interest in the complexities and often unstated assumptions behind the use of data in economic models.

Hatanaka tests the following hypotheses: (1) that the constant coefficient model is "workable" in the short run (1 to 3 years) and in the long run (7 to 10 years), in terms of comparative predictive power; (2) that variations in the coefficients over time are random, in 13 and 21 year periods; (3) that the coefficients show trends in the period 1929-1950; (4) that war conditions such as those of 1941-1945 do not disturb the coefficients so greatly as to invalidate the use of input-output analysis for mobilization purposes; (5) that changes in the relative prices of inputs can account for substitution among them (of energy sources, in the specific tests); (6) that input functions should include a fixed flow independent of output, in addition to a flow proportionate to output.

With respect to hypotheses (2) to (6), the author concludes that time variations in coefficients are not random; that the changes are in fact trends in at least some industries; that the coefficients in 1941-1945 diverged so greatly from those of 1947 as to make doubtful the usefulness of the constant-coefficient model for mobilization planning; that there is some inconclusive indication of price-induced substitution of energy inputs; and that the prediction errors are not explained by inclusion of a constant-flow term in each production function.

Since the only coefficient estimates available to the author were those for 1947, he designed indirect tests of his hypotheses as to their changes, in terms of movements in the residuals or error terms in the input-output prediction equations. Such tests require only estimates of each industry's total output and flow to final demand, in constant (1947) prices. For any industry in any year, the difference between its observed output and its observed flow to final demand is its observed production for intermediate use, and the discrepancy between this last figure and the value for it predicted by the input-output model is the above-mentioned residual. In their recent study, Arrow and Hoffenberg have also taken the movement in this residual as their measure of change in an industry's input-output coefficients.¹ Their independent and much more elaborate investigation of coefficient trends overlaps this part of Hatanaka's work. They too found distinct evidence of trends, although their complex models explained these with only limited success.

¹K. J. Arrow and M. Hoffenberg, *A Time Series Analysis of Interindustry Demands*. Amsterdam 1959.

Hatanaka's account of his tests of input-output as a predictive device, occupying more than half the volume, will probably be the subject of greatest interest to most readers. The objective has shown itself to have a certain elusiveness, the nature of which is embodied in two questions. First, what particular formulation stands for "the" input-output theory, so that statistical rejection of the model would signify disproof of the theory? Second, what criterion should be used for acceptance or rejection of even one model? The inability of input-output advocates and critics to come to agreement on the range of answers to the first question underlay much of the strong feeling that characterized earlier debate on the subject. On this point Hatanaka holds the broad view (p. 83): "The hypothesis of the input-output model states that out of all the possible models derived from different model-building specifications there exists at least one input-output model such that the errors in this model are acceptable for the purpose of input-output research. . . . We must continue to test various models obtained from different model-building specifications until we either find a satisfactory model or exhaust them all[,] concluding that none of the models has an acceptable level of error."

Since the fixed-coefficient model is the only one tested in the present volume, the more relevant question here is that of the specific test criteria. The general position of input-output proponents is that probability measures of significance are inappropriate. Since estimates of future output levels will be undertaken in any case, the effectiveness of input-output technique should be judged by its comparative performance in competition with less elaborate alternative models.

This comparison method is the basis of Hatanaka's tests, referred to as hypothesis (1) in the second paragraph of this review. In his terminology, an input-output model is proved "workable" if its errors of prediction for a given set of test observations are less or no greater than those of an alternative model. His comparison tests are the most extensive undertaken so far, and the first to be published using the elaborately prepared 1947 coefficients. They measure the aggregate errors in industry output predictions, pairing input-output against each of the following "global" models: (1) final demand projection (a constant 1947-base ratio of each industry's output to its production for final demand); (2) time series regression of each industry's output on final demand, with coefficients estimated from the period 1929-1940 (plus 1946-1947, for the short run); (3) time series regression of each industry's output on GNP, with coefficients estimated from 1929-1940 (plus 1946-1948, for the short run); (4) indirect demand projection (a constant 1947-base ratio of each industry's output to total production for intermediate demand by all industries).

In each case, comparisons are made for short-run and long-run periods. And for almost every comparison series, tests of three types are run, in terms of total or weighted average errors. Technical reasons and insufficient data led to omission of some industries from the tests. Since this gave a very heavy weight to agriculture, which yielded an especially poor input-output prediction for 1950, the author presents some comparisons both excluding and including agriculture. The tables of test results as a whole are favorable to the

input-output method, but with sufficient qualification to warrant a summary:

1. Input-output is clearly superior to final demand projection in the short run by every test. In the long run, it is also superior, except in two of the three tests including agriculture.

2. Input-output is superior to regression on final demand in the short run for all 1949 tests and for 1950 excluding agriculture. The long-run tests are inconclusive, with input-output superior in some tests and inferior in others. One set of long-run tests shows input-output to have marked superiority for the class of industries with the largest fraction of output going to intermediate demand, a result in keeping with the input-output rationale.

3. Input-output is superior to regression on GNP in the short run, except in two of the 1950 tests including agriculture. Its advantage is especially great, even when agriculture is included, for the 10 industries with 80 per cent or more of their output going to intermediate demand. The long-run results are mixed. Here again input-output is far superior for the class of industries with high percentages of output going to intermediate demand.

The long-run comparisons of input-output with the two regression models are rendered uncertain by the fact that lack of data beyond 1950 necessitated the use of different test periods for the competing methods: input-output predicted backward from 1947 to the individual years 1937-1940, and the regression models used 1929-1940 data to predict outputs for the years 1949-1950. Hatanaka offers evidence to support his belief that input-output errors—and therefore the test results—would have been about the same had 1940 coefficients been available for predicting 1947-1950 outputs.

4. In virtually every test, input-output is inferior to a model using constant 1947-base ratios of individual industry output to the aggregate intermediate outflow from all industries. But why Hatanaka presents this alternative "model" as a possible predictive device is a puzzle. What would be the source of estimation of the necessary predictor—the future annual aggregate production for intermediate use by all industries?

In addition to the contents so far described, the author presents a 54-page account of the meaning and criticisms of the static open fixed-coefficient model which a reader should find moderately clear and adequate. There is also an excellent 20-page summary of earlier empirical tests. The extensive discussion of how observation errors can affect the meaningfulness of econometric applications is an important contribution and reminder, as Morgenstern emphasizes in his enthusiastic foreword.

Though generally cautious, Hatanaka is too optimistic about the degree of accuracy assured in input-output tables by the process of cross-checking and balancing. He writes (p. 104), "In the 1947 tables the column sum and row sum are equal for each industry and sector. However, this does *not* mean that the observation errors were eliminated either from the column and row sums or from each entry. It *does* mean that these observation errors probably are not overly significant." Economists who have worked directly in the construction of input-output tables know that this conclusion does not follow simply from the equality of row and column totals for each industry.

Mathematical symbols and equations are plentiful in the volume, but the

author generally follows the admirable practice of stating his propositions verbally as well. Occasionally the language is awkward and unclear, and sometimes it is misleading to the point of error. For example, the symbol $\varepsilon_i(t)$ is defined verbally as "the global measures of the changes in input coefficients" over time (p. 98), and is repeatedly so referred to, though in fact it includes in addition all the consequences of observation errors, the separate existence of which Hatanaka has taken such pains to distinguish. It must be added that he never commits this error in his formal development or applications. On the whole, this is an excellent book, in purpose and achievement.

AMOR GOSFIELD

University of Pennsylvania

Consommation et épargne. By JEAN-CLAUDE EICHER. Paris: Sirey, 1961. Pp. vii, 165. NF 15.00.

Professor Eicher's book is one of a series of studies in economic research concerned with such topics as the power of monopoly, business cycles and money, and fiscal systems and the common market, which have been subsidized by the French Ministry of Education. It starts with a presentation of the Keynesian consumption function in a style reminiscent of the better U.S. textbooks. Then follows a discussion of the standard post-Keynesian literature including most of the important contributions, with particular emphasis on the Duesenberry formulation. Eicher is very critical of the simple Keynesian function, and more favorably disposed toward Duesenberry's.

However, the major emphasis is placed on Milton Friedman's permanent income hypothesis. Characteristically like many of Friedman's students, which Eicher was, he accepts the Friedman hypothesis enthusiastically; in fact makes it his own by conviction, and devotes a major part of the work to explaining the Friedman theory, often paraphrasing the reasoning contained in *A Theory of the Consumption Function*. This presentation is especially important in making available a major U.S. contribution to French-speaking economists.

The third, and most interesting part for those already familiar with Friedman's classic, is concerned with statistical verification of his hypothesis. Although part is taken over from Friedman, Eicher does present some new materials. For example, he cites a time series of consumption expenditures and disposable incomes of a small German sample of salaried families consisting of four persons close to the average income of all salaried families. Their incomes increased regularly from 1950 to 1958. Since, by hypothesis, no transitory factors were present, the consumption function fitted to the data almost goes through the origin and the coefficient of correlation is close to 1.

Turning to aggregates, Eicher calculates the marginal propensity to consume from official U.S. national income data for the period 1929 to 1955, and finds that the marginal propensity to consume is higher than for the subperiods 1929-1941, and 1930-1949. If the abnormal periods 1931-1935 and 1942-45 are excluded, the long-term propensity is even larger. So far,

this is in accord with Friedman. However, the propensity for 1929-1941 is larger than for 1930-49, which Eicher finds difficult to reconcile because the latter is a longer period. He claims that the difference is due to the inclusion of consumer durable expenditures rather than depreciation as in the case of the Goldsmith data originally cited by Friedman. Perhaps a different explanation is possible, since during the Second World War, the consumption function was clearly depressed. The inclusion of these years lowers the marginal propensity for the 1930-1949 period.

Consumption expenditures and disposable income (including gifts) are then compared for twelve countries for the period 1950-1955. Eicher finds that for only four countries the average and marginal propensities are similar, thus conforming to the Friedman hypothesis. In two countries, Australia and New Zealand, special circumstances such as unusually large liquid assets and rapid price and income advances can explain the discrepancy. The other countries seem to conform more closely to the Keynesian hypothesis since the marginal propensities are clearly lower than the average. However, with the exception of Holland, a longer period, 1950-1958, helps to bring the two propensities closer together.

Budget studies from six countries are cited which show a typical flattening out of consumption as income rises. Eicher's explanations are somewhat tortuous, in claiming they do not contradict the Friedman theory. For example, he argues that permanently low-income families are not likely to respond to surveys and if they do, they would not declare income from charity and relief. They are frequently omitted by survey design, and low-income families that are interviewed are those whose incomes are temporarily depressed. On the other hand, high-income families who are permanently at the top do not respond to surveys, while those who do are temporarily well situated and still cling to older habits.

Since Eicher offers no criticism of the Friedman theory, he acts perhaps like a lawyer for the defense. This reviewer remains unconvinced, since at least for him the U.S. aggregates in the postwar period still conform to the post-Keynesian notions, particularly if due cognizance is taken of the major rise in saving by private pension funds. Nevertheless, this book is an important contribution by one of France's younger and promising economists.

MORRIS COHEN

St. John's University

Intermediate Economic Theory. By GEORGE MALANOS. Philadelphia: J. B. Lippincott Co., 1962. Pp. xiii, 540. \$6.50.

To paraphrase the author, this book is intended to meet the needs of students in the upper-division undergraduate curriculum who are studying price theory, microeconomics, or general economic analysis. It is in terms of this objective, then, that the book should be evaluated. Although the author states strongly that the discussion is kept free of mathematical proofs and arguments, the student would find it helpful to have more than a passing familiarity with mathematics. Numerous proofs are presented with a heavy reliance on geometry.

As to its structural features, the book is clearly written and well organized. It has a special merit in presenting many of the analytical results as propositions, and then demonstrates their proof. This makes it easier for the reader—and the nonprofessional student—to grasp what the author is trying to say and what he is trying to prove. A special merit, too, is the fact that the author is generous in depicting the development of various analytical concepts through the course of economic thought. This presents the reader with a better perspective of the significance of the topics under discussion. At times, however, the historical method is responsible for some confusion in the limited discussion given to some of the earlier writings after they have been introduced. This points to one of the general shortcomings of the book, the failure to draw together many diverse comments about a given subject into an integrated treatment. The author should not be condemned alone for this, however, since there is much difference of opinion by economists on many of the subjects discussed.

After a very lucid and excellent introduction to the meaning of economic theory, economic history, and normative economics, the book is divided into five parts. These follow rather closely the usual presentation of microeconomic analysis—the equilibrium of the household; the equilibrium of the firm, capital, interest, and profits; general equilibrium; and monopoly, oligopoly, and monopolistic competition.

Part I is extremely well done. It presents a very clear description of the nature of utility theory and brings out well the differences in approach between cardinal and ordinal concepts of utility. The student is given an elementary introduction to some of the more sophisticated notions of utility as developed by Kaldor, Hicks, von Neumann, and Samuelson. There is some question, however, whether the broad-brush manner of treatment adds to the student's knowledge or confuses him. Part II in general is written with the same high quality as Part I. The theory of the firm and production theory are presented in terms of both long- and short-run conditions. Some may have doubts as to a discussion of equilibrium of the industry and full employment equilibrium that is presented in microterms without relation to pertinent macroanalysis and without considering the welfare implications; although welfare functions as they relate to production are treated.

Part III does not seem as well organized nor as well presented as the earlier parts. It is concerned primarily with aspects of distribution theory, primarily capital and interest and profits. A very good discussion of some earlier thinking is presented in the review of the ideas of Ricardo, Jevons, Böhm-Bawerk, Wicksell, and Knight. The reader is a little disappointed in the rather brief attention given to general equilibrium in Part Four. The last part of the book presents some of the models other than those of pure competition—monopoly, monopsony, oligopoly, duopoly, price leadership, and monopolistic competition. These in general are adequate reviews of the formulations of standard authors in these fields.

In general, this book is quite different from most of the books in intermediate theory. It is refreshing in its approach, and scholarly in its presentation. It should be well received by the instructor; in fact there is some

danger that at times the author is directing his attention to the instructor (and his colleagues in the economics profession) rather than to the undergraduate student. It would have helped if the author had preceded each section with a statement as to what the following chapters are about, what types of problems are to be discussed, and what understandings are to be derived. In this respect, the book lacks teaching organization. Some of the topics do not seem to fit well into the context in which they are presented. There also is an excessive reliance on curves to prove points with an undue assumption that the student has become familiar with the underlying concepts through exposure to a prior course in elementary economics. True, the author is torn between repeating basic principles or omitting too much. Perhaps the decision here went too far in the direction of omitting necessary explanatory materials.

Among the introductory views expressed by the author are several that should appeal to the reader, such as that economic theory should be concerned with tracing causal relations and building replicas of the real world, that generalizations should be deduced from observations and experience, and that the historical method should be concerned with more than mere description as it seeks to explain in an orderly and systematic manner what is happening in the economic sector. At times, the reader is not sure that these objectives are always achieved, that some of the presentation becomes esoteric rather than an aid to understanding and explaining economic reality.

In evaluating this volume as a possible textbook, one must bear in mind that its focus is upon a closed competitive system and that its emphasis is on microeconomics. The fact that a number of other topics might have been included—for example, a more adequate treatment of wage theory (since interest and profit theory were given considerable attention), or a more extensive discussion of full employment equilibrium—would perhaps be irrelevant and beyond the scope of the volume undertaken by the author.

RUEBEN E. SLESINGER

Economic History; Economic Development; National Economies

The Real National Income of Soviet Russia since 1928. By A. BERGSON.
Cambridge: Harvard University Press, 1961. Pp. xix, 472. \$8.75.

This is an important book. It brings to a conclusion an immense job of reconstructing and analyzing the Soviet national income. Previous volumes were confined to calculations expressed in the prices of the respective years. To obtain meaningful growth rates it was, of course, necessary to express these rouble figures in constant prices, which is a formidable task. Teamwork is essential in a project such as this, and it is certainly no criticism but rather a matter for praise that Professor Bergson was able to utilize the research of talented colleagues whose help he generously acknowledges.

The results as presented give us national income by use in constant as well as current prices for the years 1928, 1937, 1940, 1944, 1950, and 1955.

They do so in a number of variants, using constant rouble prices of different years as they stand and adjusting them to correspond to the factor-cost concept. There is a wealth of more detailed information relating to household consumption, communal services, government, defense, gross investment, etc. There are stimulating comparisons with U.S. growth rates in earlier historical periods.

Everything is thoroughly documented; and the large quantity of detailed supporting evidence provides valuable food for thought about all sorts of topics. The results of all these calculations are carefully contrasted with estimates made by other analysts. There is enough in this book for scholars to chew over for years. Therefore, whatever question marks or criticisms may be found later in this review, it must be clearly stated that no one interested in the subject can afford to miss this book. Apart from the "Sovietologists," it should also make good reading for those who value statistical and analytical ingenuity, and who appreciate the energetic and patient pursuit of facts and figures in the face of a variety of obstacles.

The reviewer once launched a perhaps excessive assault on an earlier book in this series. What concerned him then was the treatment of agricultural incomes. This was based on value percentages in virtually unknown prices, and the margin of error seemed untenably large. These objections, whatever their validity, do not apply to the present volume. Thanks to more liberal publication of data in the USSR, and to some very thorough research work, the agricultural calculations are now based on actual quantities and prices. The available statistics are used with great skill and accuracy. When the results appear to be questionable on grounds of rough political commonsense, it is clear that the commonsense picture may be wrong and Bergson right.

Yet it follows from the methods used in analyzing farm output that the whole of the margin of error falls upon peasant consumption in kind which is the residual. This needs to be borne in mind in assessing Bergson's proposition that a working collective farmer in 1937 had a real income higher than did "ordinary workers below the rank of foreman" in Soviet industry. This would be politically and economically a most important fact, for it would help to explain the slowing down of industrial growth around 1937 (there would be acute difficulties in labor recruitment), and also the harsh anti-peasant measures which were taken shortly afterwards. But the reviewer continues to feel lingering doubts. The 1937 harvest was exceptionally good, and there is ample evidence that the distribution of grain to peasants reached very high levels. The 1936 harvest was a very poor one, and for much of the calendar year 1937 the peasants must have been suffering from the after-effects of the 1936 harvest. This does not seem to have been allowed for.

But even accepting the 1937 calculations as a basis, a further question arises concerning agricultural incomes. For example, for 1952 Bergson shows farm incomes in kind in constant prices to be higher than in 1937 (p. 337). True, there is a difference in territorial coverage, but this was balanced by the reduction in peasant numbers due to war and migration. Since there was also a large increase in the value of peasant sales in free markets, which must have more than offset the decline in the real value of collective farm cash

distributions and the increase in taxes, one is left with the remarkable conclusion that the peasants were better off in 1952 than in 1937, which was the best year of the 'thirties. Would such a conclusion be consistent with the known state of Soviet agriculture at Stalin's death? Possible sources of error are exaggerations in official farm output statistics, which Bergson indeed warns us about, and possibly also an underestimation of production expenses in kind, especially within the private sector.

Very interesting questions are raised by Bergson's illuminating discussion of "adjusted factor cost." It is not always quite clear, at least to the reviewer, precisely what it is that is being claimed in this connection. At times all that Bergson appears to say is that, despite their many imperfections, actual Soviet prices net of turnover tax and subsidies are the least objectionable of the available weights. With this proposition one can agree, the more so because Bergson presents his data using alternative weights, so that anyone who believes that unadjusted rouble prices should be used is provided with indices in such prices also.

However, in some passages Bergson puts forward a claim that prices are conceptually right in a Soviet-type economy, for the measurement of welfare and of production potential. In a reply to Peter Wiles, he points out that the proper welfare criterion to adopt must relate to planners' preferences and not consumers' preferences. Quite so. But this raises some very difficult issues. What are planners' preferences? Clearly we cannot assume that they are identical with the goods and services actually produced or provided. After all, when the Novozhilov-Kantorovich school of Soviet economists argues that prices of factors of production should reflect their relative scarcities *in relation to planners' preferences*, the latter are defined as the general goals of the plan, and the whole point of that school's criticism is that existing Soviet prices do not reflect such relative scarcities. They would certainly deny that it would be sufficient for their purposes to eliminate turnover tax and subsidies.

Nor is it a matter merely of charging a standard sum for the use of capital and land (Bergson experiments with such charges). In their view these charges should be greatly differentiated to take into account varying degrees of scarcity, opportunity-cost, etc. They argue that if prices were so fixed, planners would rationally choose different means to achieve desired ends, i.e., that the pattern of production would be different with planners' goals unchanged. Bergson seems to take the view that because relative wage rates in 1937 reflected a free market for labor, and retail prices enabled supply and demand approximately to balance, average prices of that year have some special meaning in terms of welfare, etc., provided they are net of turnover taxes and subsidies. But if planners make decisions involving the use of labor in a sector where, probably without their being aware of it, opportunity cost is very high, if prices do not even pretend to reflect this situation, and if intermediate products, capital and land are administratively rationed, we seem far away from values related to welfare or production potential.

Peter Wiles argued that canal building was a conspicuous example of waste. Viewed as a means to an end, and not as part of a final bill of foods, canals

seem indeed to have been wasteful; the Soviet writer Tvardovsky recently claimed that Stalin chose canals because he wished the great works of Stalin to be visible from the planet Mars. However, in another sense canals then become ends in themselves, an integral part of planners' preferences. In still another, they may be seen as evidence of a clash between the realization of production potential and an extra-economic preference for particular means. Space precludes pursuing this discussion further. It is only right to repeat that Bergson seems justified in using these conceptually impure prices as weights, because alternatives are even less satisfactory.

One wonders why any effort was devoted to reconstructing the Soviet national income for the year 1944. Prices had little meaning when shortages of every kind were so acute, and much of the necessary information for that year is lacking or ambiguous. The figures for free-market turnover seem unbelievably small.

The methodology of deflating by price indices is the subject of a stimulating discussion. In calculating the increase of volume of consumption from 1928 to 1937 in 1928 prices, Bergson deflates by an index derived from revaluing the 1937 basket of goods in 1928 prices, i.e., his weights are 1937 weights. Arguing against Jasny's 1926-27 price deflator, he maintains that his (Bergson's) version is the logically correct one. Why? Certainly Jasny was not justified in using only early-year weights and presenting them alone as correct. But when Bergson does use 1928 weights his result is very close to Jasny's. Surely the familiar index number problem does not permit us to describe one set of weights as more correct than the other.

Finally, a point concerning the implied volume indices of production. Bergson's tables and calculations are in principle confined to national income by use, not by origin. In this way he might be thought entirely to avoid the pitfalls which beset those who, like Nutter, Seton, Hodgman and others, endeavor to construct output indices. But, of course, production figures underlie the Bergson calculations, directly or indirectly. This is most clear in the case of the investment index. For example, he uses Moorsteen's machinery indices. Anyone endeavoring to calculate either price or volume indices for machinery faces the familiar and very awkward problems of how to value new products, of comparability, changes in design, inadequate statistical coverage, etc. The dangers of error on the part of even the most careful scholar are very great. To say this is not to cast aspersions on either Bergson or Moorsteen. Far from it. They know this very well themselves, and often say so. The point is simply to emphasize that these difficulties cannot really be resolved. Needless to say, the results remain of the greatest interest. Thus Moorsteen's price index shows that machinery prices in 1937, using 1937 weights, were actually lower than in 1928, despite the intervening inflation. The use of 1928 weights makes a great difference to the rate of growth of both machinery output and the national income. No wonder Soviet statisticians obstinately refuse to recalculate their official growth rates for the period before 1950 into prices other than those of 1926-27. Their political masters might well be shocked by the results.

One can only end by again expressing grateful thanks to the author for providing students of the subject with such vast quantities of valuable material in so clear a way, and for giving us so many subjects for discussion.

A. NOVE

*The London School of Economics
and Political Science*

France and the Economic Development of Europe, 1800-1914: Conquests of Peace and Seeds of War. By RONDO E. CAMERON. Princeton: Princeton University Press, 1961. Pp. xviii, 586. \$10.00.

The literature of international movements of capital ranges from primarily political studies like Herbert Feis's *Europe, The World's Banker*, to such economic analyses of statistical data as are associated with the names of A. K. Cairncross, Brinley Thomas, and Albert Imlah. There are relatively few works that have both virtues. The classic example is Leland Jenks' *Migration of British Capital to 1875*, a book that combines the research in depth so prized by the historian with quiet competence in its handling of financial matters and with exceptional felicity of style. In Cameron's study of the French experience, we now have a similar economic history in the full sense of the term.

A more detailed comparison of the two works is suggestive. Jenks' *Migration* is more concentrated in its emphasis, more even in its coverage and distribution, more unified in its development. Cameron's study is broader. He sees the export of capital as only one aspect of a larger French contribution to the economic development of other countries, a contribution embracing the work of French entrepreneurs and technicians abroad, the instruction of foreign students in French schools, and the example and lessons offered by French law and political institutions. The result is a significant gain in conceptual scope. But it is achieved at some sacrifice of architectonic harmony.

Cameron's strong point is international finance and the capital market, and it is here that he has made his greatest substantive contribution. No one, with the possible exception of Bertrand Gille, has worked longer or more effectively exploring the public and private manuscript sources of banking history and the related diplomatic and political archives. His researches have taken him to a half-dozen countries; and a remarkable flair for evidence has enabled him to locate and open for the first time important documentary deposits whose riches are yet to be fully exploited. This alone would be enough to place economists and historians in his debt.

As a result of these researches, Cameron has been able to revise and fill out considerably our knowledge of the golden age of French foreign investment banking—those decades from 1852 to 1882 when the *Crédit Mobilier*, its associates, imitators, and rivals took the lead in covering Europe with railroad track and with a network of banks that came to play their own developmental role in the countries of their establishment. His largely original discussion of the competition for concessions and the ups and downs of

company finance is a remarkable case study of the interplay between business and politics and offers interesting analogies with the maneuvers that attended the development of the oil industry a half-century later.

Equally new is the material on the contribution of French enterprise and capital to the early industrial development of Belgium and Germany. The support of French investors, acting through private merchant banks like Rothschilds and Hottinguers, goes far to explain the burst of promotion in Belgian metallurgy and mining in the 'thirties and 'forties that helped make Belgium the most precocious industrial nation on the Continent. In Germany, French investments were more closely associated with direct enterprise: capital from the northern coal field, in conjunction with Belgian and British interests, exploited a number of major Westphalian mines; French technicians, supported by an alliance of French and German capital, played the decisive role in the development of the German nonferrous metals industry; and the largely French-founded and managed Phoenix Corporation was the first and largest integrated concern in the German iron industry, accounting in 1855 for almost a sixth of total Prussian output. It was about this time that French influence reached its high-water mark. The following years saw French managers and technicians replaced by German personnel, French holdings taken over by German investors. The story of this transfer and the rise of Germany to the position of competitor to France in the backward economies of eastern and southeastern Europe is still a comparatively unexplored area of research.¹

At this point, two questions arise: (1) What were the consequences of this export of capital and skills for the development of the French economy? and (2) What are the implications of these accomplishments for our understanding of the factors determining the rate and character of French economic growth?

To the first Cameron's answer is qualified. The export of institutions, knowledge, and talent, he feels, cost France nothing; on the contrary, they brought valuable returns in political security and in the mutually advantageous growth of partners in an international market. The export of capital, on the other hand, yielded a mixed harvest. The large sums sunk in the paper of impecunious foreign governments often brought orders for French manufactures (though far less than the amount of the loans). But even then, they went mostly for the waste of pomp, corruption, and armaments, and did far less than direct investments would have done to promote the economic development of the countries concerned. Though most of these state funds continued to pay interest punctually up to the First World War, they were by any standard of long-run rationality a poor investment. It was not only that war and revolution brought inflation and repudiation and wiped out a large share of French foreign holdings (Russian bonds alone accounted for more than one-fifth of these in 1914);² the fact was that, long before the war, many

¹ See *inter alia* J. Legge, *Kapital- und Verwaltungsüberfremdung bei der Industrie und den Verkehrsanstalten Deutschlands von 1800 bis 1923/4* (Halberstadt, 1924); B. Brockhage, *Zur Entwicklung des preussisch-deutschen Kapitaleports* (Leipzig, 1910); G. Diouritch, *L'expansion des banques allemandes à l'étranger* (Paris and Berlin, 1909).

² According to Harry D. White, *The French International Accounts, 1880-1913* (Cam-

of these mismanaged governments were paying the rapidly mounting interest on their debts only by new borrowings, and that the pyramid of credit would eventually have collapsed in any case.³

The question still remains whether French economic growth would have been more rapid had this capital been placed within the country. Cameron has his doubts. He remarks (p. 504) that there is no reason to assume that this money would have been invested in France in the absence of foreign outlets. After all, French industrialists could have borrowed if they wished; if they did not, he argues, it was frequently because investment would not have paid anyway.⁴

He may be overestimating the rationality of this decision. Yet in any event, he seems to me to put his finger here on an important determinant of the distribution of French investment. From the Pereires on, the interest of French financiers in foreign operations reflected in large part the limitations of home demand. It was not so much quantity as quality that was lacking: the self-respecting firms avoided medium and long-term borrowing as much as possible, resorting to outside help only in time of distress, precisely when the lenders were not interested. Too often credit was linked to rescue operations rather than healthy growth. Small wonder that foreign operations, particularly flotations of government securities, looked more promising to banks like the *Crédit Lyonnais* and the *Société Générale* than domestic lending.

On the other hand, one should not underestimate the influence of these banks on the allocation of French investment (p. 504). A number of scholars have noted the importance for the movement of British capital of the institutionalized preference of the London market for overseas issues.⁵ *A fortiori* was this true of France, where the large branch banks, in which was concentrated a substantial share of the country's disposable small and medium savings—the kind of savings whose owners were most desirous of and susceptible to “expert” advice—committed themselves by the 1880's to foreign invest-

bridge, Mass., 1933), pp. 275 n. 1, France lost some 23 billion francs in foreign holdings during the war, or some two-thirds of her *net* investments abroad. On the basis of Cameron's estimate of some 46 billion francs in net foreign assets in 1913 (p. 79), the loss amounted to one-half.

³The best analysis of the subject remains that of H. D. White, *French International Accounts*, pp. 272 *et seq.* Cameron has not attempted an independent estimate of the rate of return of French holdings abroad comparable to the one effected by Cairncross for Britain (*Home and Foreign Investment, 1870-1913* [Cambridge, 1953], ch. ix). Discretion here was probably the better part of valor: it is not clear whether one can attach real meaning to calculations that do not and perhaps cannot take into account capital losses as a result of bankruptcy and default.

⁴It is an interesting and important question how much French enterprise avoided long- and medium-term borrowing for nonrational reasons. The newly published study of Jean Bouvier, *Le Crédit Lyonnais de 1863 à 1882: les années de formation d'une banque de dépôts* (Paris: S.E.V.P.E.N., 1961), offers abundant evidence of the emphasis of French firms—even large corporations—on self-financing as a virtue and a way of business.

⁵Cf. H. S. Foxwell, “The Financing of Industry and Trade,” *Economic Journal*, XXVII (1917), 502-22; F. W. Paish, “The London New Issue Market,” *Economica*, n. s., XVIII (1951), 1-17.

ment. In the light of the developmental role of investment banks outside of France, especially in Belgium and Germany, it seems unreasonable to assume away the contribution that French banks might have made to home industry had they shown more imagination and initiative. To be sure, as Cameron notes, the periods of greatest export of capital were also those of rapid domestic capital formation.⁶ Yet while this may refute the argument that capital exports "starved" French industry (p. 504), it hardly demonstrates that the two outlets for investment were not competitive.

The second of our questions—the implications of Cameron's findings for our appreciation of the factors shaping French economic growth—is one to which he does not address himself directly. In particular, he does not choose to re-examine the much debated allegation that entrepreneurial shortcomings were a major determinant of French economic retardation in the light of his own findings. And this is the more unfortunate because, for one thing, the subject needs explicit clarification and few scholars are so qualified as he to elucidate it; and for another, readers will inevitably be inspired to draw their own unguided conclusions.

One can, to be sure, infer certain elements of Cameron's interpretation. Thus he seems to offer a variation on the traditional assumptions of slow industrial development in France (p. 64 f.): reasonably rapid growth until the 1880's, then a "long and costly depression" that "adversely affected the psychology of entrepreneurs and investors with results that have not yet been completely erased" (p. 71).⁷

The above might seem to imply acceptance of entrepreneurship as a significant factor in the slowing of French growth after 1882. And yet I am not sure. Cameron is not inclined in the last analysis to lay much weight on psychological attitudes (a major element in entrepreneurial behavior) as an autonomous or persistent determinant of growth. "The emphasis is on institutions": "a rational legal and juridical order, based on a secular conception of society and allowing for geographical, occupational, and social mobility of

⁶ In this connection it would be helpful to have year-by-year estimates of domestic capital formation and national income to set alongside those of export of capital. Whether it is feasible to produce such estimates is another matter. Here we must wait on the work of Jean Marczewski's team at the Institut de Science Economique Appliquée in Paris. Cf. the first two volumes in the new series "Histoire quantitative de l'économie française," ed. J. Marczewski: Vol. I. J. Marczewski, *Histoire quantitative: buts et méthodes*; J. C. Toutain, *Le produit de l'agriculture française de 1700 à 1958*, Part I: *Estimation du produit au XVIII^e siècle*; Vol. II. J. C. Toutain, *Le produit de l'agriculture française de 1700 à 1958*, Part II: *La croissance* [F. Perroux, ed., "Cahiers de l'Institut de Science Economique Appliquée, Series AF, No. 2, Suppl. No. 115 (July 1961)"] (Paris: I.S.E.A., 1961).

⁷ The simple substantive question of France's absolute and relative rate of economic growth still remains to be explored. Traditional assumptions of slowness are disputed by Raymond Aron, *France Steadfast and Changing* (Cambridge, Mass., 1960), p. 45, in so far as the twentieth century is concerned. And the forthcoming study of Maurice Lévy on the French economy in the first half of the nineteenth century may also argue for more favorable estimates. Needless to say, revisionist assertions are not likely to settle the issue; but they do indicate the need for more accurate information, particularly of a comparative nature.

persons"; "given the appropriate institutional environment, individual psychological motivations have a way of adapting" (pp. 505-6).

This last generalization seems to accord with the position advanced by Cameron in a number of earlier analytical articles on the character and determinants of French economic development.⁸ His argument is a refinement of the Clapham thesis, that France's industrial retardation has been (or was) the result of inadequate material resources, of the scarcity of coal in particular. As Cameron once put it in a felicitous phrase, the French economy suffered "from a lack of minerals in the diet."

As for entrepreneurship itself, there is no way of knowing from his book how Cameron would react to the inferential judgment of one reviewer, who wrote: "Although Cameron's purpose is not to refute the popular theory that French businessmen have always been shortsighted and unenterprising, the whole burden of his story is that such a stereotype does not fit nineteenth-century France."⁹ His work certainly alters the usual image, but it is not yet clear how, and his silence may be an act of discretion. Certainly there is a great deal more we need to know about this matter before arriving at conclusions. For example:

How did French entrepreneurship abroad compare with entrepreneurship at home? (There is no reason to assume that the one is the same as the other, either in intrinsic potential or performance. On the contrary, the presumption is that emigrant entrepreneurs are the products of a process of social selection.)

Why do those French entrepreneurs who operate abroad do so? (Presumably in order to obtain a higher rate of return. But why the differential? Cheaper raw materials? Minerals unavailable at home? What of opportunities for new men at home and the recruitment of talent into domestic enterprise?)

How does French enterprise abroad compare with that of other countries? How does it perform under competitive conditions?

If Cameron does not address himself to these questions directly, we are nevertheless in a far better position to consider and answer them thanks to his work. By assembling this impressive body of evidence of the diffusion of French intellectual, institutional, technological, and financial influence, he has corrected an excessively low evaluation of France's economic role in an age of industrial revolution. He reminds us that through the first three-fifths of the nineteenth century the French economy was in many areas the most advanced in the Continent, well ahead of the German, to say nothing of the more backward nations to the south and east. And he offers impressive illustrations of the energy and imagination with which the French exploited the opportunities offered by this differential. Here lies his major contribution: he has done much to restore our sense of proportion.

In so doing, he has marked out a path for future research. An enormous

⁸ These are cited in his bibliography, p. 545.

⁹ Gordon Wright, in *The Journal of Modern History*, XXXIII (1961), 446. This theory, if held, is presumably popular in the literal sense of the word; I know of no scholar who has ever proposed or accepted such a stereotype.

task lies ahead: to see and understand the diffusion of institutions and techniques as part of an international process of development; to fit countries other than France into the stream; and to build our analyses on comparative data that permit isolation and evaluation of the several economic variables. It is not often that a book is important both for what it says and what it does not say, for the information it gives and the guidance it promises in future explorations. This is such a book. Cameron is to be congratulated.

Economic Growth in the United States: Its History, Problems, and Prospects.

By SUMNER H. SLICHTER. Edited by JOHN T. DUNLOP. Baton Rouge: Louisiana State University Press, 1961. Pp. xiv, 196. \$5.00.

These five chapters represent a revision of Professor Slichter's five Merrill Foundation lectures delivered at Tulane University in April 1954. The revision was left incomplete on Slichter's untimely death in September 1959. John Dunlop, as Slichter's literary executor, refrained from carrying the revision further; his principal substantive contribution is a valuable introduction, which points out the importance with which Slichter regarded these particular lectures in summarizing and setting forth his economic philosophy.

The titles of the five chapters (lectures) are respectively, "Some Discussions of Economic Growth and Evolution," "The Growth in Output per Man-Hour in the United States," "Some Elements in a General Theory of Private Demand," "Conditions and Institutions of the Economy to Increase the Demand for Goods," and "The Future of Economic Institutions in the United States." They were left in widely different stages of revision, with the second lecture (on the growth of productivity), apparently closest to completion. At any rate, this second lecture is at once the most scholarly of the five and the most immune from the *ex cathedras* and *ipse dixit*s of Slichter's extracurricular style in his later years.

Let us turn then to this second chapter, which should also be the longest remembered of the book under review. It formulates what I propose to call "Slichter's Law," a statistical generalization that over-all labor productivity accelerates over time. Evidence in favor of this proposition is collected from a broad range U.S. economic history, and Slichter has every confidence that the proposition will continue to hold for at least the middle-run future. (This reviewer harbors skeptical doubts, if hours of labor fall further and the labor force shifts further away from "goods" to "services.") It would likewise be interesting to see to what extent Slichter's generalization applies to other countries in various stages of development.

In conformity with his generally sanguine outlook, Slichter regards the acceleration of productivity as favorable to the maintenance and increase of the U.S. growth rate. This is obvious enough, if one is not concerned with aggregate demand. In terms of the Harrod identity (for which Slichter does not conceal the scantiness of his regard), $G = (S/c)$, Slichter's law implies a

steady fall in the marginal capital-coefficient c , and accordingly (barring a fall in the saving-ratio S), it implies a steady rise in the growth rate G . But in terms of the Domar equation (which Slichter does not consider at all in this connection), Slichter's Law, if verified, is a source of pessimism rather than optimism. If net investment I increases full-employment output by $(\sigma_0 + \sigma_1 t)dt$, rather than by (σdt) as in Domar's original, and if the corresponding increase in purchasing power is, by the Keynesian multiplier process, (dI/α) , where α is the marginal propensity to save, the Domar moving-equilibrium path for investment at full employment becomes

$$[I = ke^{\alpha(\sigma_0 t + .5\sigma_1 t^2)}].$$

This is even more difficult to maintain, and no more stable, than the standard Domar time path

$$(I = ke^{\alpha \sigma t}).$$

The last paragraph, of course, criticizes Slichter implicitly from a Keynesian point of view which he did not himself accept. His third chapter, on consumer demand, is devoted to explaining why; it parallels at many points an *Atlantic Monthly* article on "The Passing of Keynesian Economics." Slichter's main point is that consumption, far from a passive resultant of contemporaneous disposable income, depends on assets and future income (credit), and is in fact an active force with "multiplying" power of its own. This type of criticism has been taken in stride by Keynesians ever since the demonstration-effect arguments of Duesenberry and Modigliani in 1946-47. Since Slichter's Tulane lectures, furthermore, the work of Tobin and Friedman (the former generally Keynesian, the latter decidedly not) has taken a good deal of the free-will wind out of his sails. It is unfortunate that Slichter did not live to fit their results into his own surmises, particularly the Friedman permanent-income hypothesis to which he now seems to have supplied a prelude.

The other three chapters are one long running battle with underconsumptionists and stagnationists past and present. Slichter's opponents in the first chapter are Mill, Marx, Veblen, Keynes, and Schumpeter. Each is formidable enough by himself, it would appear, and it seems to this reviewer that Slichter delivers only glancing blows against most of them. (Much of his argument seems traceable to the special circumstances of the Second World War, the cold war, or public intervention generally.) Chapters 4-5 are almost equally polemical, as Slichter asserts his faith that, in the United States at least, stagnation is a bogey, and the route is ever onward and upward. With each succeeding paragraph or section I awaited the answer to the \$64 question of all such discussions: "Could we afford to disarm?" Alas, there was no answer. Indeed, the question was never raised. In default of both question and answer, the whole discussion fell rather flat.

The flatness may not be Slichter's fault, in that the manuscript Dunlop published may have been incomplete. Two or three years before Slichter's death, the reviewer heard that Slichter's Tulane lecture materials contained a definitive answer to the argument of Joseph Steindl's *Maturity and Stagna-*

tion in the American Economy (Oxford 1952). An inquiry to Slichter himself elicited a reply confirming the rumor but soliciting patience, since the manuscript was still unready for outside readers. Now, four or five years later, the published version of these same lectures mentions neither Steindl, his book, or his particular form of stagnationist dilemma.¹ This episode, of no importance in itself, suggests that on many other issues Slichter may have had more and better things to say than appear in print in this posthumous work.

Slichter backs away in this volume from certain views with which he was most widely associated five or ten years before his death. For example, he no longer wishes to maintain that the U.S. economy is or will soon become a "laboristic" one, dominated by its trade union movement. As for secular inflation, he still considers it a small price to pay for a "free" trade union organization, but now believes (p. 187) that:

the rise of white-collar workers will mean a slight dilution of the strength of the trade union movement and more of a balance of power on the whole between unions and employers. Eventually, the increase in the number of white-collar workers may cause a disappearance of the problem of creeping inflation, which is a sort of symbol of the excessive strength of the unions of manual workers.

The optimism which so endeared Slichter to the business community (apart from his inflationist heresies) stopped short at the borders of the developed world. There is nothing of the Pollyanna in his admission (p. 152) that:

The educational arrangements for educating the ablest young people . . . seem to be more highly developed in Russia than in any other country. . . . Russia should be able comfortably to outstrip the West in technological progress.

And so for "the rest of the world—especially . . . much of Asia, the Near East, and much of Africa," Slichter borders on the submissive, forecasting that (p. 192 and footnote):

the vacuum created by the collapse of western colonialism will [not "may"] be replaced by dictatorships operating under Russian tutelage and with the help of Russian administrative and technical experts. (The dictatorships would come anyway because they are an effective way of making modern technology available to ignorant and poverty-stricken peoples, but the incentive to establish them is increased by the investment of western capital in these regions. The seizures of the plants of western corporations in southeastern Asia, the Near East, and in much of Africa will [again, not "may"] supply the dictatorships with much-needed capital.)

M. BRONFENBRENNER

University of Minnesota

¹The Steindl dilemma can be stated briefly: competitive industry is too risky to attract household savings at any reasonable interest rate, while monopolistic and oligopolistic industry is too interested in maintaining "insider" control and restricting output to attract household savings in adequate volume. In the first case, investment is less than full-employment saving because of supply considerations; in the second, because of demand considerations on the market for loanable funds.

Economic Development for Latin America. Edited by HOWARD S. ELLIS with HENRY C. WALLICH. New York: St. Martin's Press, 1961. Pp. x, 479. \$10.00.

This is a collection of papers, critical comments and discussions of a round-table of the International Economic Association held at Rio de Janeiro in August 1957. As Howard Ellis points out in his introductory notes, the main purpose of the conference was not so much to cover all possible issues in economic development but rather those chiefly involved with the supply of capital and with international economic relations.

Alexandre Kafka presents a rather theoretical interpretation of Latin American economic development. In his opinion relatively rapid progress in over-all Latin American growth has sometimes been associated with violent adverse shocks to the economic system. Such adverse shocks do not necessarily retard development; sometimes they may even precede positive growth. In the great depression, the most adverse shock in the century, there were countries, like Colombia and Mexico, which were able to get through the period with a rise in average real product. This implies that there might exist an optimum degree of adverse shock—although this does not mean, of course, that an adverse shock is necessarily better than a favorable one. (In the ensuing discussion Kafka declared that he just wanted to *explain* the positive growth effects of adverse shocks, not to *recommend* them.)

Macroeconomic global planning is defended by José Antonio Mayobre. Global programming consists in the setting of precise targets for the nation's economy. Such targets comprise not only specific projects, like the achievement of a certain steel capacity, but achievements of a more general nature, like a given rate of increase in per capita income. While fiscal and monetary policies deal with the problems of the economy on an *ad hoc* basis, global programming is an excellent weapon in the proper coordination of the nation's efforts for long-term growth.

However, the planning of targets is not enough; means have to be found to achieve them. And, according to P. N. Rosenstein-Rodan, in his paper on the "Big Push," tremendous efforts are needed to convert a stationary into a dynamic economy. To use Ragnar Nurkse's words, in the circumstances of our time, the poorer countries are not prepared to accept the inevitability of gradualness: they want to be launched into the state of self-sustaining growth; and that is only possible if a minimum amount of investment is made, sometimes irrespective of immediate needs. This is the theory of the "Big Push." Public overhead investment, in power, transport, etc., plays an important role in the process.

Roberto de Oliveira Campos discusses the problems of inflation and balanced growth. Distorting effects of inflation are felt in agriculture (supply disincentive effect), social overhead investment (bottlenecks in the saving process), balance of payments (terms of trade). There is general agreement that the strong inflationary bias in most of the underdeveloped countries, particularly in South America, derives from the fact that their growth process often finds its motivation on the demand side rather than in the entrepre-

neurs' drive to produce. Unfortunately the traditional weapons of monetary and fiscal policy are ineffective if monetary pressures come from wage increases.

The role and servicing of development capital is the subject of essays by Maurice Byé and Gerald M. Alter. The essence of economic development is structural change of a type that tends to be progressive; thus underdevelopment is not simply a backwardness in quantitative terms but is connected with certain structural features, more particularly with insufficient integration of the various sectors of the economy. While the main emphasis in Byé's paper is on the role of capital at different stages of development, Alter examines the various tests an underdeveloped country might have to face by potential investors. The mathematical models he proposes serve to demonstrate the upper limits of debt service capacity.

According to Javier Marquez's very interesting paper, the basic problem of Latin American financial institutions is a shortage of noninflationary funds. He makes a case for the fact that financial institutions are a function of economic development; the higher the level of per capita income the greater the quantitative importance of financial transactions per unit of gross national expenditure. He also makes a case for unspecialized banks because the flow of specialized funds is uneven whereas development must be a continuous process. As the investments of private financial institutions are determined by the structure of effective demand which, in Latin America, reflects sharp income inequalities and is not conducive to economic development, Marquez would prefer the establishment of public financial institutions to complement and in a certain way influence private banking.

According to Felipe Pazos, in his study on private versus public foreign investment, the relative needs of developing countries for loans and equity investment are in a ratio of 55 for loans to 45 per cent for direct investment. His main argument is that, in the long run, direct investment is costly to the developing country: United States direct investment in Latin America in fields other than public utilities is bringing an annual yield of 20 per cent contrasting with rates on loans of 5 or 6 per cent. However, as John Adler demonstrated in the course of the discussion, these figures are perhaps a little exaggerated: the effective cost of loans is probably considerably higher, around 10 per cent while the real yield on equity investments is lower; at the stage of the transfer it might reach 10 per cent but no more.

Ragnar Nurkse considered the compatibility of comparative advantage and balanced growth. Can international trade alone be the generating force for economic development? His answer is no, mainly for technological reasons; while Great Britain needed ever-growing imports to maintain the phenomenal growth of her 19th century economy, the rate of growth in the import demand of the United States, the dominant economy of the 20th century is much lower. Hence, since international trade alone cannot do the job, the demand needed to stimulate adequate expansion should be created locally, through balanced growth.

According to Gottfried Haberler, in his study of the role of the terms of trade in development, there is no statistical proof for the contention that the

terms of trade for all, or the majority, of underdeveloped countries have deteriorated; it is also unlikely that, in the long run, the terms of trade should run parallel for all underdeveloped countries. Although over the business cycle the prices of primary products do have a tendency to fluctuate more violently than those of finished goods, the degree of regularity and the magnitude of these cyclical fluctuations have been greatly exaggerated. Unfortunately, the excessive stress on terms of trade has led to preoccupation with symptoms which cannot be controlled or eliminated, especially not with unworkable schemes of price stabilization. Hence, the underdeveloped countries would be better advised to learn to live with a certain degree of cyclical instability. The impact of fluctuations should be softened in cooperation with the industrialized nations and international agencies.

The two following papers are based on somewhat different concepts. The prospects of primary products and the problem of the stabilization of the proceeds from raw material exports are analyzed by Theodore Schultz and Henry Wallich respectively. The whole world is deeply stability-conscious, income elasticity of demand for raw materials is too low, and therefore means have to be found to stabilize the incomes of primary producers. Unfortunately, according to Wallich, the prospects for pure stabilization agreements are poor. The case is better for commodity agreements including countercyclical loans and grants. Under this plan, the United States and perhaps other consuming countries, at times of declining commodity prices, would make loans to producer countries. The loans would tide over the borrowing countries financially but would also give some protection to consumer countries against an extreme upsurge of prices.

A paper on investment priorities, by Jorge Ahumada, concerned with some theoretical aspects of planning, is followed by a study by P. R. Brahmamanda of the University of Bombay, on agricultural vs. industrial development. The latter contains the traditional arguments for investments in agriculture, to reduce the hidden unemployment of rural masses, increase rural purchasing power and let the general economy benefit through higher employment, higher rates of growth and ultimately higher consumption standards. Thus, agricultural investment operates as the lever which sets the ball of development rolling.

The last study in the volume, by Jorge Marshall on exchange controls and economic development, contains an excellent description of the uses and abuses of contemporary exchange control practices. While Marshall does not exclude the possibility that there might be some arguments for exchange controls, in the case of flight of capital for instance, or as a means of taxation, his general conclusion is that freedom of exchanges has given a better climate for economic expansion in Latin America as well as elsewhere. Exchange controls are often the consequence of domestic inflation and its effect on the balance of payments.

The volume will serve as an excellent document to record the economic thought of Latin America in a very important stage, the stage which has just preceded the conclusion of the Alliance for Progress. The papers cover most of the representative aspects of present Latin American economic problems.

Perhaps a little more space could have been devoted to reports on the discussions which followed the presentation of each paper. Also more could have been said about operational problems—even in a debate of a theoretical nature. The lack of suitable projects is at least as great an obstacle to economic development as is lack of capital.

Membership in the conference was about equally divided between distinguished advocates of planning and *laissez faire*. Some of the planners were more convinced of the usefulness of direct than of indirect controls. They seemed to forget that less than twenty years ago direct controls, like exchange measures, had become most powerful weapons in the hands of totalitarians; this is all the more important to remember since nowadays similar methods have again been adopted in one of the most strategically located Latin American countries.

It was an excellent idea to have invited an expert in Asian planning to participate in the conference. Without exactly saying so he drew attention to the fact that Engel's Law is decisive, but only under certain circumstances. The population of huge subcontinents is still starving. The world has become so small, the five continents so interdependent that it will not be possible to isolate the economic development of Latin America from that of the rest of the world; in other words, such development will not depend any more on trade, or aid, from the United States or the Atlantic Community alone; its final success will depend also on what can be done to improve the lot of the masses, particularly in Asia, whose income elasticity of demand for food is still so high.

ARTHUR KARASZ

Bangkok, Thailand

Stanovništvo kao čimilac privrednog razvoja Jugoslavije. By MILOŠ MACURA. Ekonomska Biblioteka, Vol. 7. Belgrade: Nolit, 1958. Pp. 374.

Politika i metodi privrednog razvoja Jugoslavije. By NIKOLA ČOBELJIČ. Ekonomska Biblioteka, Vol. 10. Belgrade: Nolit, 1959. Pp. 378.

Students of Yugoslav economic affairs are here afforded a rare opportunity to look at the course of events from the viewpoint of active participants in policy formulation. These volumes in the Ekonomska Biblioteka are devoted exclusively to Yugoslav postwar economic development. They contribute considerably to our knowledge of the vicissitudes of an economy in which planning has not been able to fulfill completely its ambitious growth program. Macura makes an extensive inquiry into population and labor force as determinants of Yugoslav economic growth. Čobeljič undertakes a comprehensive study of Yugoslav development methods and policies. Both authors present their story against the background of the evolution of the country's internal economic institutions and its international commercial relations since the First World War, examining carefully the impact of population trends and development measures respectively on the national wealth.

Both books are factual and reasonably objective rather than theoretical and philosophical. Under circumstances where the latter approach presumably

would not have meant much more than wide quotation from a particular orthodoxy, this represents a definite advance. Macura and Čobeljič view sympathetically, though not uncritically, attempts of their government to deal with the problems of the postwar epoch. They take pains to show that many of the economic difficulties with which planning sought to cope had their roots in the prewar era. Čobeljič's work centers about the decade from 1947 to 1956: from the time when administrative central planning became fully effective to the years of decentralized government guidance of all essential sectors of the economy. Macura considers a somewhat longer period of time, on the basis of which some of his judgments with respect to population trends and contemporary economic development can be verified, although most of the expected long-term effect of population policies cannot presently be reliably gauged.

The arrangement of Macura's material is mainly topical, but chronological sequences are frequently used within the eighteen chapters. The author begins with a description of the demographic characteristics of Yugoslavia's preponderantly agricultural population with its low personal income and high degree of self-sufficiency. Population pressure did not change the economic structure very much between the two world wars and it has not been particularly conducive to economic growth. The Yugoslav community only started to reorganize the exploitation of its resources when confronted with new socio-economic goals after the Second World War. In spite of the noticeable structural changes that occurred in the years under review, a detailed analysis of production, national income, and employment trends in relation to population increase demonstrates that the postwar population policies succeeded only partially in solving the economic problems of the country. Macura unfortunately does not answer the question whether Yugoslavia's economic growth has simply recently become self-sustaining or whether somewhat heavy population increases, for two or three generations now, have not created some special pressure to raise the standard of living of this traditionally agrarian and, at least in Serbia, egalitarian society.

Macura correctly considers population both as a production and a consumption factor. The conclusion suggested is that population changes are at best a very secondary determinant of Yugoslav economic development. On the other hand, there is very limited evidence presented that economic development is a determinant of the size of the population, except for the customary effect of enforced urbanization and regional migration upon birth rates. Macura consequently devotes more attention to questions of the economic structure of population and the required shift of a part of the labor force from agricultural to nonagricultural occupations. He makes it quite clear that the rapid increase of nonagricultural population has been due to cultural progress at large as much as it has to economic planning.

The author contends in particular that the expansion of tertiary industries has reached an extent not compatible with the most efficient use of the country's resources. He acknowledges the need to expand industrial employment possibilities and stresses the dependence of employment upon the availability of trained labor and capital accumulation, but he also points out the rela-

tively low cost of a program aimed at improving working habits and the qualifications of labor in agriculture. He does not adequately substantiate his contention that the transfer of many young workers into nonagricultural occupations causes a significant lowering of the quality of the agricultural population. Gratifying to students of development is his reiterated conclusion that the misallocations of manpower use should be attacked by less expensive and less spectacular programs than those prevailing.

Čobeljč's monograph offers in Part I a discussion of the general problems of underdevelopment and the significance of the social system as a determinant of economic change. Part II deals with the methods and policies of development employed in Yugoslavia. Heavy emphasis is laid on the means of capital accumulation and the establishment of a structural equilibrium in the economy. Part III records achievements in increasing the means of production, income, and productivity, and in effecting some structural change. Part IV discusses problems emerging in the course of Yugoslav economic growth, such as the lags in agricultural production, price stabilization, and the financing of imports. The principal topics are the relationships between national income distribution and personal consumption, capital accumulation, and spending on social overhead; sources and volumes of capital accumulation; and the patterns and efficiency of new investments.

While Čobeljč's general conclusions are summarized at the end of the volume and technical development difficulties are extensively examined, he shows scarcely any awareness of the issues raised by the fundamental manner in which Yugoslav industrialization proceeds. The smallness of Yugoslavia as a hindrance to optimum size of enterprise is recognized but he does not stress how much this situation is worsened by the limitations and frequent redirections of foreign trade. He concedes that the lack of international investment causes procurement problems, but does not admit the heavy sacrifice in the standard of living. The slow rate of growth of personal consumption is in his view caused by insufficiently elaborate planning. The persistence of unutilized resources is also considered to be due mainly to technical problems arising from the execution of the planning program. Thus he does not consider it necessary to inquire into a possible overemphasis on medium and heavy industry capacity and into the matter of the replacement of peasant farming by collective producers. The postwar Yugoslav socio-economic system is frequently credited with being especially conducive to economic growth, but beyond stating that this system is "a historical necessity" there is little demonstration of its superiority as a factor in economic growth.

Čobeljč rightly points out that a development policy aiming at long-term effects may not yield its major results in its first decade. From this work it is difficult to establish the time perspective of Yugoslav planning. There seems to be, however, a growing awareness that the structure of investment must gradually adapt itself to the needs of harmonious development and a more balanced relationship between the various sectors. Continued, though allegedly no longer centrally administered, planning is relied upon to raise and further diversify production. Čobeljč does not consider the possibility that

the social compromises which are exemplified by worker's management and by the protracted co-existence of the collective and private sectors of the economy may be intrinsically unstable or that half-way houses may involve special problems of their own.

The events on which the two volumes under review are based are rich in situations that reveal want, not of energy, public spirit, or practical knowledge but of mastery over first principles. Knowledge of how a particular piece of planning machinery operates has not always been matched by deep understanding of its functions. There appears to be a studied effort by both authors to keep away from the elucidation of controversial issues. The use of Marxian stereotypes is fortunately infrequent. On the whole the presentation of both volumes is competent, and the interpretation of the data is sensible. Čobeljč's vast sweep is always discerning. His subject could nevertheless have been treated more evenly by dealing deductively with the main problems. Yet the student of development will find here interesting descriptions of functional and institutional approaches to production and distribution policy. A wider acquaintance with international economic literature than is revealed by the limited entries of foreign items in their bibliographies might have furnished answers to questions which puzzled both authors.

PAUL J. MEIER*

University of Massachusetts

* Deceased February, 1962.

The Role of Small Enterprises in Indian Economic Development. By P. N. DHAR AND H. F. LYDALL. Bombay: Asia Publishing House for Institute of Economic Growth, Delhi, 1961. Pp. xvi, 95. Rs 8.

In the flood of books on the role of small-scale enterprise and industrial estates in economic development this book—a result of collaboration in India between the Institute of Economic Growth and the M.I.T. Center for International Studies—provides a welcome change. Much of the previous literature views small enterprise as a basic sentimental virtue *per se*, approaching motherhood. This book, on the basis of the Indian experience, reviews and analyzes the arguments in favor of special assistance to small-scale mechanized enterprise; it sorts out those arguments that are valid from those that are at best questionable; it then uses the conclusions from this analysis to examine the program for aid to small enterprises in India and to make recommendations for changes on the basis of the conclusions.

The authors' general conclusions (pp. 20, 24, 31-32, 33-34; their italics) are as follows:

1. "Large factories can [frequently] produce the same volume of output by using less labour *and* less capital than would be used by small factories."
2. "Small firms are in fact more dependent on the external economies of a good local market, good supplies of raw materials from local dealers, and so on, than large and medium firms . . . If the Government is serious about decentralization then it must be prepared to persuade large firms to go to some

of these underdeveloped towns. Small firms will soon follow . . . [especially] if they are given encouragement by the provision of suitable facilities."

3. The main case for a special program of assistance to small enterprise rests upon the desirability of "trying to make the path of new entrepreneurship as smooth as possible . . . Any positive measures that can be taken to promote the *growth* of small firms into efficient medium sized firms will . . . be of great advantage to the [Indian] economy, since there is probably a thinness in the supply of such medium-sized enterprises.

4. Finally "there is no good case for giving small enterprises *preferential* treatment . . . The existing approach [in India] tends more and more to give special favours (preferences, subsidies, reserved areas, etc.) to small firms; the alternative approach would aim, rather, to *remove their disabilities*."

These general conclusions provide the basis for the evaluation of the industrial estates program and other programs to assist small-scale enterprises in India. With respect to the industrial estates program they find in many estates factory space is unoccupied because of the high cost of facilities or poor location of the estates; that estates in backward rural areas will be largely unoccupied unless larger firms can be encouraged to lead the way for smaller firms; that industrial estates should be "regarded not as homes for the weak and the inefficient but as nursery beds for small enterprises"; and that when this nursery-bed function has been performed and the small firms have grown into medium-sized firms, space should be provided in nearby industrial areas for the now-medium-sized firms, which should be replaced by other small firms in the estate itself.

With respect to various aspects of the general program of assistance to small enterprise in India—technical advice, supply of machinery, training, financial assistance, protection and subsidy, marketing assistance, and allocation of raw materials—the authors conclude that many parts are desirable, but the purely protective and subsidy aspects of the program should be reduced or eliminated. Stress should rather be upon providing services, information and finance at unsubsidized rates, so that the small firms can become more efficient, compete effectively, and grow.

While there are a few specific points in this analysis and series of recommendations which are questionable, I feel that the authors' general conclusions and specific policy recommendations are valid for India, to which the authors are careful to limit their analysis and conclusions. However it is of interest that A. Molinari of SVIMEZ in South Italy recently presented an unpublished paper on the Italian industrial estates program which was in general agreement with many of the Dhar-Lydall arguments.¹ Regardless of the direct applicability of the book it is certain that other countries can gain from the Indian lead and experience in this whole effort to encourage small enterprises. Therefore this book by Dhar and Lydall should be read not only in India but in any country on the threshold or early stages of an industrial development program. It is profoundly hoped that more books of this skeptical and analytic nature appear; for until now there has been far too much

¹ "Some Controversial questions concerning Industrial Estates," presented to the Madras Seminar on Industrial Estates in the ECAFE Region (Nov. 1-11, 1961).

sentiment, exhortation and description in this field and nowhere near enough objective analysis.

GEORGE ROSEN

Calcutta, India

Land Tenure, Industrialization, and Social Stability: Experiences and Prospects in Asia. Edited by WALTER FROELICH. Milwaukee: Marquette University Press, 1961. Pp. xv, 301. \$9.00.

This is a collection of essays submitted to a conference held at Marquette University in September 1959 to consider "one of the most fundamental issues confronting the economies of Asian nations: namely, the problem of land tenure and its relationship to economic, political and cultural change" (p. xi). The essays range rather widely in subject matter and in quality, reflecting differences in authors' interests and degrees of effort in preparation. Most of the papers are much narrower than the title of the book implies; they are devoted mainly to consideration of land tenure systems and land reforms in specific countries, with relatively less analysis of the interrelationship among land tenure, industrialization and social stability. (As a confession of ignorance, this reviewer is not even very certain what is meant by "social stability".)

The book is divided into three parts: Background, Land Reform Problems, and American Policies. The first part provides background in the most general sense of the term; it is a catch-all for essays that did not fit in well elsewhere. Froehlich's "Preliminary Remarks" are diffuse, and do not really get to the heart of the problem at hand. T. F. Marburg's long study of Western (mainly American) land tenure institutions and economic development, while interesting and informative, is not presented on a comparative basis relating to Asian nations, and the author does not draw conclusions of explicit relevance for Asia. It might well have been omitted. Yuan-li Wu's excellent paper on land reform and communes in Communist China is placed in Part I, evidently because it is the only study of a communist Asian country included.

The core of the book—and two-thirds of its length—is in Part II. In this context it is desirable to treat Kenneth Parsons' paper (in Part III) since it has mainly to do with land reform problems and in scope and approach is the most stimulating article of the collection. Parsons suggestively analyzes with a fairly high degree of generalization the "operative interrelationships in the village economies of Asia (and the place of tenure relations in this context) which need to be considered in programs of development and reconstruction for these economies." (p. 280). B. F. Hoselitz in a good paper has a somewhat similar approach. Among other things, he points to the conflict in land reform between welfare objectives and those of increasing output (and a marketable surplus): the distribution of land among all agricultural families makes for farms uneconomically small. This conflict comes up frequently in the papers on individual countries. Included also in this chapter is a sensible, pragmatic general paper on land reform by Lossing Buck, and a good, straightforward paper by Martin Bronfenbrenner suggesting why contemporary Asian coun-

tries are not placing major reliance on increased agricultural exports as a basis for their development programs.

There follow a series of country studies for Japan, Taiwan, South Korea, Philippines, South Vietnam, Thailand, Indonesia, India, and Pakistan. Most describe in varying degrees of detail the traditional land tenure system and the land reform programs that have been attempted, with main emphasis on welfare and output objectives within the agricultural sector. Which are the most interesting is partly a matter of taste; I thought the best to be Raj Krishna's long paper on India and Widjojo Nitisastro's on Indonesia. Krishna's paper is broad in scope, thoughtfully covering a wide variety of problems in terms of the basic issues with considerable insight. Nitisastro is concerned with the transmigration of agricultural families from overpopulated Java to underpopulated neighboring islands. The papers by P. T. Ellsworth (Thailand), H. L. Cook (Philippines), and William Bredo (Pakistan) are also good.

Part III (consisting of two essays) is a misnomer in that very little is said about American policies. Parsons assumes that United States policy is mainly to promote the economic development of Asia and, as indicated above, goes on to consider what that implies for the agricultural policy of Asian nations. The final essay in the book, by David Rowe, is the only one specifically devoted to the problem of land tenure and social stability. Rowe, using the experience of Taiwan as his major example, makes the general point that we cannot "rely entirely upon economic development for the inducing of social stability in Asian countries," (p. 294) and has specific comments on the destabilizing effects of land reform.

This book is not really aimed at the country specialist, since most of the country studies inevitably are insufficiently detailed, nor at the specialist on the role of agriculture in economic and social development, since the broader theoretical articles also are not fully developed. But it should prove useful for the economist generally interested in Asia and in land reform as it relates to economic development.

HUGH T. PATRICK

Yale University

The Achieving Society. By DAVID C. McCLELLAND. Princeton: D. Van Nostrand Co., 1961. Pp. xv, 512. \$7.95.

Robert L. Garner concluded from his experience during fourteen years as vice-president of the World Bank and president of the International Finance Corporation that differences in geography, natural resources, and availability of capital do not explain rapid development in some countries and underdevelopment in others. "I am therefore, forced to the conclusion that economic development or lack of it is primarily due to differences in people—in their attitudes, customs, traditions and the consequent differences in their political, social and religious institutions."¹ David C. McClelland presents measurements of a specific form of human motivation and shows that high levels of

¹ Meeting of the Board of Governors, IFC, Sept. 21, 1961.

that motive "recur regularly in the imaginative thinking of men and nations before periods of rapid economic growth."

The difference between Garner and McClelland illustrates the difference between an insightful observer and the scholar who contributes to the scientific discipline of economic psychology. This is an exact parallel to the difference between assertions about the role of confidence or mistrust in cyclical fluctuations and measurements of certain forms of attitudes and expectations which are shown to be widespread before the economy turns up or down. Prior to McClelland's work economic psychology contributed to the understanding of short-range changes in economic processes; his studies deal with much slower changes and encompass centuries and a variety of diverse cultures. Irrespective of whether change in national income during a business cycle or over centuries is studied, economic psychology demonstrates that it is possible and useful to go beyond asserting that economic development is the result of human behavior by measuring specific psychological factors and showing their correlation with subsequent economic processes.

In several earlier books McClelland and his co-workers isolated and measured certain motives (motives are relatively stable and enduring personality traits) primarily through responses to standardized picture tests carried out with school children and college students. Measurements of one of these motives, need for achievement, called *n* Ach. by psychologists, are extended in the new book to distant societies (e.g., ancient Greece, pre-Incan Peru, England from 1400 to 1800) as well as to contemporary societies.

Among several ingenious forms of measurement, just the most important instance will be mentioned here. McClelland assembled 21 imaginative stories from school books used by second- and fourth-grade children in each of 23 countries around 1925, and in each of 40 countries around 1950. Through standardized coding of these stories he obtained *n* Ach. scores and found them to correlate with measures of the degree of subsequent economic growth (both after 1925 and after 1950). Economic growth was measured in terms of real national income (in Colin Clark's international units) and in terms of electric power produced per capita, in both cases initial levels being taken into consideration (gains or losses over expected values were calculated from regression lines). McClelland emphasizes the many "obvious flaws of the data." Nevertheless, the manifold data presented must be viewed as strongly supporting his major hypothesis, namely, that certain psychological forces, roughly measured by high *n* Ach. scores, make universally for rapid economic growth. (It should be noted that later in the book *n* Ach. scores are expanded into an achievement syndrome which includes Riesman's other-directedness.)

According to McClelland the link between high *n* Ach. (A) and economic growth (C) is the presence of a large number of entrepreneurs (B). He is much more successful in demonstrating the relationship between A and C than between either A and B or B and C. Statements such as "Behaving in an entrepreneurial way is practically an alternative way of saying that a person has high *n* Ach." do not suffice to demonstrate the relation between A

and B. No evidence is presented in the book for the assertion that: "The businessman is more apt to be involved in new, risky or challenging problem situations in which there are many unknowns and he must improvise new solutions rather than apply existing specialized knowledge." How about the scientist or the engineer, or even in certain cultures the artist or the priest—do they face fewer new and challenging problems than the businessman? Why should additional energy, inner concern with achievement, concern with standards of excellence, concern with getting ahead, stress on hard work—to list some of the component parts of the achievement syndrome—manifest themselves exclusively and at all times in entrepreneurship? The terms entrepreneur, businessman, and manager are used indiscriminately. Sometimes trickery and even dishonesty are emphasized; lack of originality and routine in business behavior remain unnoticed. Uncritical esteem of all forms of entrepreneurship leads McClelland to close his book with a call for the U.S. government to subcontract aid to underdeveloped countries to private U.S. business firms so that "better men" might be employed in foreign aid.

The basic problem concerns McClelland's universalistic notions. We may admit that certain motivational traits may be described in universal terms and that economic growth is a meaningful concept in ancient as well as present societies, yet it is hardly conceivable that business behavior would not take different forms in different societies. Reliable studies about how businessmen actually behave are rare, even in this country at the present time, and McClelland, who constantly stresses the function of empirical research, can hardly be blamed for not having undertaken comparative studies of business behavior in different countries at different times.

If it were true that in different cultures different links might provide the connection between the presence of a large number of young people with high achievement motivation and economic progress, some of McClelland's conclusions about the current position and prospects of the United States would need to be reappraised. To be sure, according to one set of measurements n Ach. scores for the United States are low at present: After a sharp increase from 1830 to 1890 the scores dropped to the level of 1850 in 1950. (McClelland justifies these findings by a parallel movement in the number of patents issued per capita; yet the number of patents taken out is surely dependent on custom and circumstances rather than reflecting innovating activities alone.) According to the major set of measurements, n Ach. scores in the United States increased from 1925 to 1950 and were in 1950 among the highest in the world (slightly exceeded only by Australia, France, Canada and, surprisingly, Spain). And yet McClelland writes with reference to Galbraith that in an affluent society production is slowed down while in an achieving society it is speeded up. But possibly a mass-consumption economy represents a new phenomenon in human history in which motivations of millions of people rather than of a few business leaders account for the rate of economic growth. If so, then the role of business investment in nineteenth century England may not serve as a paradigm in the present-day United States.

Disagreement with some details and even with one major point does not detract from the solid achievement McClelland's book represents. Even

though the book is not the last word in the study of motivational factors responsible for economic growth, it is more than a beginning or a pointer toward new paths. Future studies of economic development cannot disregard what has been presented by McClelland.

GEORGE KATONA

The University of Michigan

American Economic History: The Development of a National Economy. By LANCE E. DAVIS, JONATHAN R. T. HUGHES, AND DUNCAN M. McDOUGALL. Homewood: Richard D. Irwin, Inc., 1961. Pp. xiii, 408. \$7.50.

The authors have pioneered an intriguingly different approach to an area of economics which has, in many schools, been relegated to a secondary position in the study of economics. Here is a well-written, one-semester text which aims to put the study of U.S. economic history back where it belongs—in “the core of the study of economics” (p. vii). This text is a teaching vehicle, and even a casual survey of the book emphasizes the fact that “it is apparent that the teacher of this book will need somewhat more sophistication in both the worlds of history and economics than is required by many economic history textbooks” (p. vii). In those schools where economic history is taught in the history or social science department, or where it is handled by an economist not trained in history, this book would not, in the reviewer’s opinion, be a wise choice as a text.

The authors make no attempt to present a chronological survey of the development of America from colonial times to the present. In fact, the colonial period is not covered except to the extent necessary to prepare the stage for analysis of specific economic phenomena. As stated in the preface (p. vii), “We have tried to make possible a more general use of the materials of economic history by relying upon the use of simple economic analysis to explain the main patterns of America’s economic development since the early nineteenth century.”

The theoretical background for the study of economic development is provided in a section on the allocation of resources in a free-enterprise system. Here the student is introduced to marginal analysis, since it is assumed that this text will be used “as the basis of the first course in economics” (p. vii). Income accounting and income distribution are sketched to give a foundation for much of the analysis of forces aiding in the development of the United States. Classical dynamics and the neo-Keynesian growth models are presented, followed by a description of the fluctuations in economic activity in this country.

Having erected the framework around and into which economic activities may be placed, the authors examine in separate sections the economic areas which to them constitute the main stream of economic development in the United States. No attempt is made to correlate time periods between these areas. However, where time relationships are necessary or aid in the analysis of a sector the chronological periods are established. The place of the demographic variable is well presented, although those economists stressing labor union development will not find an exhaustive treatment of that topic. De-

velopment of the demographic sector always brings about a shifting of responsibilities in the public sector. Hence, government control of business as well as the role of government as a source of investment capital is described.

In the treatment of the development of savings and investment a good job has been done in sketching the ways and means used in this nation to accumulate the necessary capital to mobilize our resources. To the reviewer, however, this section lacks sufficient coverage of the monetary system, and the banking system is not treated in sufficient depth to give a beginning economics student a rounded foundation for relating pricing and the capital market. The authors justify their approach to the discussion of the development of the monetary standard by saying, "We have done this because of our concentration upon economic rather than social and political aspects of the nation's growth and development" (p. 216).

Logically following the study of capital accumulation is a section on geographic expansion, market expansion (both domestic and foreign), and transportation development. The structural changes in industry and agriculture, resource bases, and technological improvements are presented in separate chapters. In these chapters the emphasis is upon an analysis of changes in the sector being presented with a minimum of descriptive material and/or the chronology found in the usual presentation of such developments. In a closing section the U.S. experience in economic development is summarized, and is followed by an excellent discussion of the difficulties, in fact impossibilities in most cases, of trying to fit or force any pattern of economic development into the existing economic framework of an underdeveloped economy.

Here is a delightfully different treatment of a vital area of economics. The book's usefulness as a text depends upon the quality of the instructor, the level of the course-offering, and the placing of the course in the economics curriculum. If used as the authors suggest it should be excellent; if circumstances or desired results are different from those mentioned, it is suggested that a "standard approach" text be used.

JOHN W. CHISHOLM

Louisiana State University

Programas de estabilización económica en América Latina. By G. A. COSTANZO. México: Centro de Estudios Monetarios Latinoamericanos, 1961. Pp. 143.

Mr. Costanzo's theme in this series of lectures is that internal and external disequilibrium are barriers to economic development. The principal kind of internal disequilibrium in which he is interested is inflation. External disequilibrium is defined in market terms as a payments deficit causing a loss of reserves or requiring the government to depreciate, impose exchange of import controls, or to acquire short- or medium-term loans abroad. Unlike Nurkse he does not include a full-employment criterion. Internal disequilibrium (inflation) is the most important cause of balance-of-payments problems in underdeveloped countries, and its magnitude is measured by the balance-of-payments problem.

Inflation originates with the creation of credit by the central bank usually at the instance of a government that lacks the fiscal resources to pay the costs of its development schemes. In addition it must, in the usual case, finance the deficits of state-owned enterprises, e.g., the Argentine and Brazilian railroads and Bolivia's *Corporación Minera*.

Costanzo estimates the quantity of money that the central bank of a "typical" Latin American country can create without raising the price level would be 1 per cent of national income if the national income were growing at the rate of 5 per cent per year. The basis of this estimate is the fixed relationship that is alleged to exist between the quantity of money and money income in these countries.

The argument with respect to the consequences of inflation is cogently stated though scarcely novel. Inflation redistributes income to some businessmen and reduces the real income of workers without raising the level of private saving since luxury consumption by the beneficiaries is encouraged. Investment is distorted. And, worst of all, foreign capital is discouraged from entering the country.

The analysis is quite general; it is intended to apply to all underdeveloped countries whatever their particular kinds of economic institutions or stage of development (with the exception presumably of planned socialist countries). Qualification of the argument by reference to different situations is entirely lacking and the case studies used in illustration include economies as dissimilar as those of Argentina and Bolivia.

The point of view is that of the IMF, of which the author is a high official. It will not convince those who argue that the prescription of balanced budgets and central bank restraint is trivial for countries desirous of development but possessing fundamental defects in their economic institutions. Furthermore, they might contend, it is possible for the central bank to become an active agent in accomplishing changes in structures prior to a period of growth—but with some inflation as a consequence. The policies of the Bank of Mexico in the Cárdenas period are a case in point.

The studies of specific countries (Argentina, Bolivia, and Paraguay) are taken as instances of recent monetary stabilization after prolonged inflation. In each case the inflation was accompanied by a failure to achieve much in the way of growth and, if it is yet too early to tell whether stabilization will be followed by growth (and continuance in political power of Señores Frondizi, Paz, and Stroessner) at least Costanzo sees many hopeful signs—particularly the gain in their foreign exchange reserves.

These brief studies are the best part of the book even though one cannot avoid thinking that the failure of the Perón regime had a deeper basis than monetary imprudence. Here is an excellent technical account of the various devices by which monetary restraint was imposed. It must have been of particular interest to the central bank technicians to whom these lectures were originally directed.

ROBERT R. EDMINSTER

Statistical Methods; Econometrics; Social Accounting

Statistique et observation économique. By ANDRÉ PIATIER. Volumes 1 and 2. Paris: Presses Univ. de France, 1961. Pp. 972. NF 20; NF 22.

The author of this excellent work is *agregé* (lecturer) in the Facultés de Droit et des Sciences Économiques in Paris, also professor at the Ecole Pratique des Hautes Etudes. He has produced an outstanding introduction to statistics and econometrics for students of economics. The book is a text for third-year students of *licence*. (This corresponds roughly to our MA degree.)

The first part of the two-volume work discusses methodological questions. A short chapter deals with the history of economic thought, another with the history of statistics. Chapter 3 treats the part of mathematics in economics. In Chapter 4 the author gives his views on some specific questions like causality in economics, economic laws, the subjective view, etc.

The second part deals with statistics proper. There is an account of censuses, the administration of statistics, sampling, and the organization of statistics. There are also chapters on central value, dispersion, and index numbers. In the latter one misses, especially in a French book, a treatment of the outstanding contribution of F. Divisia to the theory of index numbers, which is fundamental to much later work. Another chapter deals with errors, graphical methods and presents the usual ideas connected with time series. There is also a short chapter on correlation and regression along conventional lines. A very short account of probability theory is followed by a discussion of the usual statistical distributions (binomial, normal, Poisson, log-normal). The last chapter in Volume 1 deals very briefly with significance tests and related matters.

We find in Volume 2 a very competent and modern discussion of econometrics. The author starts with the construction of econometric models, then follows up with a short presentation of the principles of micro- and macro-economics and aggregation. One misses here the discussion of the ideas of H. Theil on linear aggregation, which would fit in very well with the elementary account given in the book, and a mention of the important contributions of the French school of econometricians to the aggregation problem (Roy, Nataf, Malinvaud, etc.).

The second chapter brings a discussion of static and dynamic models and the introduction of stochastic elements (shocks). There is a short section on multicollinearity, which uses Frisch's confluence analysis, another on identification and the estimation of parameters. Starting from the classical method of least squares the author presents the method of simultaneous equations (Cowles Commission) and recursive models (Wold).

Perhaps the most interesting chapter is the third, which exhibits some results of econometric research. Early work by Gini (1910) and Lenoir (1913) is mentioned, as well as the work of H. L. Moore and Henry Schultz. There is a most interesting account of the econometric analysis of mail services in France, 1873-1936, by E. Morice. The author next presents a short account of work by J. Milhau on the demand for wine in France, 1919-1933. There is also the description of a study by M. Brichler on the demand for

rail travel in France, 1921-36. After a discussion of point and arc elasticity of demand the author proceeds to Engel curves. Results in various countries are here compared with income elasticities for several commodities derived from French data by J. Benard, L. Goreaux, J. Voranger and others.

American investigations of the demand for automobiles are compared with similar studies by H. Faure and J. Maurice for the French automobile market 1927-1938. There is a short account of the study of C. Fourgeaud on metropolitan traffic in France. The author also presents the study of M. Verhulst and D. Fourgeaud on the French flax market 1946-1952.

The following part of the book treats business cycles and business barometers. There is a short account of business cycle theories, the cobweb theorem, acceleration models, and multipliers. The model by Frisch (1931) is briefly discussed. There follow sections on the models by Lundberg, Metzler and Modigliani, Samuelson, Harrod, Hicks, and Smithies.

This theoretical chapter is followed by an empirical one. Hanau's econometric model of the pork cycle is discussed, and some empirical results of Tinbergen's investigations of business cycles are presented. Various results on the consumption function in the United States by several authors are given. The large models for a whole economy by C. Clark, L. R. Klein and R. Frisch are shortly described.

The next chapter deals with business cycle tests and presents most interesting materials. There follows a section on macroeconomics. National accounting is most thoroughly discussed. The role of the government is stressed which is particularly important in France where many industries are nationalized. There is an interesting chapter on the comparison of Western and Soviet economic budgets. The book ends with a short but competent presentation of Leontief tables and their applications. The usual statistical tables are included in the book.

The reviewer concludes that this is a most competent and useful introductory text. He finds it superior to any introductions to econometrics or texts in economic and business statistics in English that he knows. It would be very desirable to have this book translated into English, especially because it presents much of the excellent empirical econometric work in France which is not easily accessible.

GERHARD TINTNER

Iowa State University

Primenenie matematiki v ekonomicheskikh issledovaniyakh. (Application of Mathematics in Economic Investigations.) Edited by V. S. NEMCHINOV. Moscow: Sotsekgiz, 1959. Pp. 486.

The greatest significance of this collection of essays lies in its physical existence, in the fact that it was published. For, appearing under the editorship of a full member of the Academy of Sciences, it constitutes an official announcement that the use of mathematics in economics need not be anti-Marxist and, indeed, is even to be encouraged in a socialist society. This change in policy may, in a few years, make quite a difference in the quality

of Soviet economic literature. In fact, its influence can already be noted in the current journals and books, including a second volume of the present work which has just appeared.

In his introductory chapter, Nemchinov admits that "among our economists there is a certain rather strong prejudice against the application of mathematical methods in economics" (p. 7). It is, he explains, a reaction against the Austrian marginal-utility and the Anglo-American econometric schools' use of mathematics to promote "their pseudoscientific, apologetic conceptions." With responsibility for the shortcomings of Soviet economics thus placed on the West, Nemchinov turns to establishing Soviet priority in the fields of input-output and linear programming. Though these claims unduly magnify the importance of Russian contributions compared to that of Western work, they are far from groundless. The more the reader is impressed, however, with the promise shown by the early Soviet work, the more appalling becomes the fact that it was allowed—not to say compelled—to remain undeveloped for twenty or more years.

Soviet priority in the field having been established, the rest of the book settles down to business. Over one-third is devoted to a paper by V. V. Novozhilov, "Measuring Inputs and their Results in a Socialist Economy," which will be discussed below. It is followed by a translation of Oscar Lange's paper, "Some Observations on Input-Output Analysis," which appeared in *Sankhyā* in 1957. L. V. Kantorovich's 1939 paper which is the basis of Soviet priority claims in linear programming is reprinted. It has been translated in *Management Science*, July 1960. A new Kantorovich paper follows which surveys the possible applications of linear programming. The book is completed by two papers on the transportation problem, one on the mathematics of linear programming, one on numerical methods for linear programming, and an annotated bibliography prepared by A. A. Korbut. The numerical methods paper, by G. Sh. Rubinshtein, presents several methods very concisely and suggests at least one novel modification of the usual procedures (p. 454).

Novozhilov's paper might be more descriptively entitled "Determining the Socially Necessary Labor Value of All Inputs." "Many economists," he observes, "suppose that the measurement of inputs does not require higher mathematics" (p. 131). But in fact, finds Novozhilov, because a minimizing problem is involved, so is higher mathematics. The economic problem of the communist society, as he sees it, is to minimize the total labor necessary to secure the "planned accumulation" of capital and the "program of production of final outputs" (p. 165), given available resources and technologies. We are assured that the treatment of consumer demands as known restraints is appropriate under communism. For when, "because of the high level of labor productivity, distribution comes to be according to needs, then for many products the output can be calculated from scientifically based norms of consumption" (p. 165n). The minimization of total labor required is accomplished iteratively. First, "tentative norms of effectiveness" are established for each means of production. Novozhilov identifies these norms of effectiveness with Lagrangean multipliers, the so-called shadow prices of

linear programming, but he avoids the word "price." Using these norms, the "differential [labor] input" of each process for producing each final output is computed just as we would compute the cost of the process. For each product the process with the smallest differential input is chosen, and the total utilization of each factor is computed and compared with the amount available. The norms of effectiveness are revised upward for factors used in excess of availability and downward for those not fully utilized. The process is continued until no further revision is necessary, whereupon the optimum has been found. The names are strange, but the process is very familiar. In the modification of the "communism" model for "socialism," the word "price" begins to appear, and consumer requirements are determined by "collective regulation."

Though the recognition that economics involves minimization and maximization and that these involve mathematics seems a bit belated in Soviet economics, it has at last been achieved. A beginning has been made, and it may well prove to be an important one.

CLOPPER ALMON

Harvard University

Procjena nacionalnog bogatstva po područjima Jugoslavije. (Estimate of National Wealth of Yugoslavia by Areas.) By IVO VINSKI. Zagreb: Ekonomski Institut NR Hrvatske, 1959. Pp. iv, 282.

Dr. Vinski has been devoting most of his time since 1953 to the problems of estimating national wealth of Yugoslavia and its various areas. His first major publication in this field was *Nacionalno bogatstvo Jugoslavije* (National Wealth of Yugoslavia), Zagreb 1957, an extract of which was published in the International Association for Research in Income and Wealth volume, *Income and Wealth*, Series VIII, pp. 160-92. In this study he presented his methods of estimating national wealth and the basic source material, the estimate of wealth of Yugoslavia as of the end of 1953, and an estimate of the growth rates of national wealth in 1953 and 1954. Using the same methods and considering the specific conditions in various areas he then undertook the pioneering job of estimating—as of the same dates—the national wealth and the growth rates of Serbia (with the autonomous regions of Vojvodina and Kosmet), Croatia, Slovenia, Bosnia and Herzegovina, Macedonia, and Montenegro, and presented his results in the book under review. Furthermore, Vinski presented in a communication of 1959 to the Yugoslav Statistical Society an estimate of fixed assets for Yugoslavia for the period 1946 to 1958. Later in the same year he submitted to the Sixth European Conference of the IARIW estimates of "National Product and Fixed Assets in the Territory of Yugoslavia, 1909-1958."

In estimating the national wealth of Yugoslavia by areas as of the end of 1953, Vinski uses the direct estimate approach. For the estimates of growth rates of national wealth for 1953 and 1954 and for the estimates of national wealth in other time periods he uses Goldsmith's perpetual inventory method. He consistently anchors his estimates in 1953 and expresses them in 1953 prices.

The principal source materials for Vinski's estimates of national wealth were censuses of fixed assets in both the socialist sector of the economy and in the public health services carried out between 1953 and 1955. The censuses showed both the new replacement value and the depreciated value of fixed assets at prices established by a government commission. Since these censuses covered only about 30 per cent of the total wealth, Vinski estimates the remainder of the reproducible wealth and the value of land on the basis of a mass of other information, which he uses with great ingenuity. Rates of growth of national wealth in 1953 and 1954 were obtained from official data on investment and depreciation in the socialist sector, complemented by Vinski's estimates of these magnitudes for the private sector.

The study here reviewed shows in a systematic quantitative fashion for the first time the great differences in the structure and the level of economic development among various people's republics and autonomous regions of Yugoslavia. Thus the index of per capita reproducible wealth (national average 100) in new replacement value in 1953 is estimated at 45 in Kosmet, 62 in Macedonia, 74 in Montenegro, 80 in Serbia and in Bosnia and Herzegovina, 117 in Vojvodina, 126 in Croatia, and 185 in Slovenia (p. 40). On a depreciated value basis the indexes are somewhat higher for the first five areas and lower for the latter three. This difference is caused by the relatively lower rates of investment between 1945 and 1953 in the latter areas. Vinski ascribes these great differences in the per capita wealth by areas primarily to the differing historical background of various areas, although a certain role is attributed to the differing natural resource endowment.

Postwar policy especially favoring economic development of Yugoslavia's own less developed areas tends somewhat to reduce the inherited differences in the per capita reproducible wealth. Thus the growth of fixed assets in 1953 was 4.5 per cent for the country as a whole, while for the people's republics it was as follows: Serbia 2.3, Croatia 2.8, Slovenia 3.2, Bosnia and Herzegovina 11.1, Macedonia 11.6, and Montenegro 21.3 per cent (p. 55). As a consequence of the feverish investment activity during the postwar period, the regional composition of fixed assets and their average age has undergone profound changes.

Fundamental changes have also taken place in the ownership of assets. With the exception of rural and small urban residential buildings, agricultural and handicraft tools, livestock, and other agricultural inventories, practically all reproducible wealth has been socialized. However, even when wealth has remained in private ownership, as did about 90 per cent of agricultural land, changes in the institutional and political framework of the economy have exerted pronounced influence on the value of wealth according to kind and sector of ownership. This, in turn, affects the over-all value composition of total national wealth. Here is the most outstanding example: while the prices of reproducible wealth have risen between 1938 and 1953 on the average 18.7 times, the prices of agricultural land have risen only 6.5 times, and of urban land in centrally located parts of cities only 2 times. Low prices of urban land were due partly to the fact that rents were controlled and kept on a symbolic level and partly due to the fact that nationalization of urban land was expected and actually soon carried out.

The whole field of the quantitative analysis of national wealth and its growth is relatively new and its procedures are not standardized. The dependability of estimates can be only as good as the underlying data and the perspicacity of the man undertaking them. It would be a miracle if Yugoslav statistical and other economic information, which are not characterized either by completeness or great original reliability, were capable of providing Vinski with sufficient data for estimates of national wealth to which no exception could be made. But to probe into single estimates one by one it would be necessary to evaluate all of the underlying source material. Actually Vinski himself has been eager to revise and to improve his estimates, e.g., in regard to the valuation of agricultural land and the handling of depreciation, as new information becomes available or a different method of estimation becomes advisable.

When Vinski ascribes the great differences in the per capita wealth by regions primarily to varied historical background of these regions, in my opinion he does not pay enough attention to the differing rates of population growth in the various regions as a basic factor affecting the per capita level of national wealth in 1953. In view of the fact that, for example, the population of Bosnia and Herzegovina rose between 1880 and 1953, according to the figures of the Yugoslav population expert Macura, by 146 per cent and that of Macedonia by 119 per cent, while that of Slovenia rose by only 35 per cent, the population factor plays a key role. Since population continues to grow in various areas at vastly different rates, the population factor and the policy of the government to speed relatively the development of less developed areas play a basic role in the contemporary rates of growth of both reproducible wealth and of real per capita income in various areas. In a multinational state like Yugoslavia, these matters have not only economic but also far-reaching political implications.

Even if subsequent revisions and refinements of Vinski's estimates should indicate that his present estimates are off by a substantial margin, his work is of a pioneering nature and will serve as basis for any further development in national wealth studies in Yugoslavia. For its wealth of information and the light that it throws on the Yugoslav economy, the book under review will be greatly appreciated by all those interested in the development and the changing structure of the Yugoslav economy as a whole, and of its specific regions in particular.

Economic Systems; Planning and Reform; Cooperation

Ogólne problemy funkcjonowania gospodarki socjalistycznej. (General Problems of the Functioning of the Socialist Economy.) By WŁODZIMIERZ BRUS. Warsaw: Państwowe Wydawnictwo Naukowe, 1961. Pp. 353.

Model building, it appears, is not a monopoly of Western economists. The volume under review is an outcome of a relatively short-lived but at times quite lively discussion in the years 1956-1957 concerning the model of the Polish economy. The author, a professor of economics at the University of

Warsaw, was one of the the most prominent protagonists in the debate. His book represents a summary of his views with regard to the functioning of the socialist economy in general and is not confined exclusively to Poland.

The major part of Brus's book is devoted to the discussion of two basic models of the socialist economy: the centralized model; and "the model of a planned economy with the application of a market mechanism," which the author simply calls the "decentralized model." The difference between them lies in the decisions which every socialist system has to make. According to Brus there are three major categories of such decisions: the macroeconomic ones which form the prerogative of central planners; decisions concerning individual consumption and employment which, as a rule, are solved through the market; and the third category which Brus defines as "current economic decisions" and which pertain to such problems as the volume and structure of inputs and outputs, the choice of sources of supply and direction of sales, forms of workers' remuneration, and others. In the opinion of the author, models of the socialist economy can differ only according to whether the third category of decisions is made by central planners or by enterprises. It may be added that for the purpose of his argument Brus assumes the absence of a private sector in the economy.

Brus's description of the centralized model, although interesting, does not introduce any new elements except as he stresses the active role of money in the market for consumer goods and labor, as opposed to its role in the relations between the planners and enterprises and among the enterprises themselves. In connection with the latter he criticizes frequent attempts to justify the low level of prices of machinery and equipment as necessary for stimulating technological progress under socialism. According to him, such reasoning has no place in a situation where capital is allocated centrally and the enterprise is indifferent about cost. Altogether "the centralized model' is characterized . . . by a deep mistrust for money accounting which is treated as being too general, anonymous, nonindividualized, and hence not providing an adequate picture of gains and losses from the viewpoint of the planners."

Brus has little use for the centralized model. He criticizes it in the accepted fashion (lack of elasticity of output, absence of proper cost accounting, elimination of the initiative of individual enterprises, and growth of bureaucracy). However, the major objection to the model voiced by him and by other Polish economists in the past concerned its failure to take into account the role of the law of value in the socialist economy. Consequently Brus proceeds to discuss in detail the working of the law under both static and dynamic conditions. His main purpose is to provide a strict definition of the extent to which the law of value operates under socialism. He defines the law as the tendency of price relations to conform to value relations, and in this connection he criticizes those among the Soviet economists who claim that the law of value is utilized when prices are set which do not correspond to their respective values. Obviously, the planners often set prices well above or below average costs. What Brus objects to is calling this "planned utilization of the law of value" while, in fact, the law is being disregarded.

In the author's opinion, the law operates in static conditions within the

framework of planners' preferences, and any allocation of resources contrary to it represents a departure from the optimum. It is not fully valid under dynamic conditions since in making autonomous investment decisions the planners must take into account the various capital-output ratios and technological improvements in addition to the criterion of profitability. Brus believes that equalization of the rates of profit can serve only as a supplementary factor within the limits drawn up by the development plan, and cannot influence the choice of the latter. Furthermore, investment decisions should not be subordinated to the currently existing structure of the economy, subject to the law of value operating today, but should take into account the "perspectivistic aspect" of the law and the economic structure of tomorrow. Consequently, Brus arrives at the conclusion that the extent of the working of the law of value under socialism is restricted by the presence of planners' preferences, particularly in the field of investment.

After this excursion into the realm of theory, or what he calls "the analysis of the substance of resource allocation," Brus goes back to his model building, discussing the forms of allocation within the decentralized model. He emphasizes at the outset that the use of a market mechanism in the allocation of resources is not, in theory, opposed to the premises of a planned economy, and the decision as to whether the market or the direct orders are finally to be chosen for the purpose of allocation should be on the basis of their usefulness as tools for the planners. For the latter, Brus reserves all "direct" decisions concerning the distribution of national income and the allocation of investment funds among various sectors of the economy. All other decisions are to be made by the enterprises which are, in turn, influenced by "indirect" planners' preferences concerning taxes, depreciation allowances, prices and wages. In the author's view the Yugoslav system corresponds most closely to the decentralized model and since that system has been discussed in great detail both in Poland and elsewhere, only the broader aspects of the model are analyzed.

Brus clearly favors the decentralized as compared with the centralized model. He sees the main advantages of the former in its ability to achieve a higher degree of adaptability of supply to demand, and a more rational allocation of resources than in the case of the latter. In his opinion the decentralized model can provide for a "balanced growth" of the economy by way of eliminating or reducing some of the most glaring disproportions, and it frees the planners from the necessity of making numerous detailed decisions, thus enabling them to concentrate on the more important problems. Brus rejects the standard objections to the application of the market mechanism, most of which deny the possibility of setting up a system of flexible equilibrium prices. So long as scarcity relations are taken into account, there is no reason why the planners could not come up with a rational price system, particularly at the present stage in the application of mathematics to economics.

It may be added that while Brus concentrates on the economic sides of the decentralized model he does not ignore its social aspects. He emphasizes the democratic character of the model in which individual and collective interests

coincide. This, among other things, is what makes the decentralized model realistic and thus preferable to the centralized model which, by and large, chooses to ignore the individual.

The discussion of the two models is preceded by a short history of the development of socialist economic doctrines, starting with Marx and ending with the Bukharin-Preobrazhenski controversy. As is to be expected this particular chapter met with enthusiastic response in Poland where some of the reviewers hailed it as "the first attempt in the Marxist literature to restore to socialist economics its own history."

This short review does not do justice to Brus's book. Although in places, particularly in discussing the law of value, the author does not avoid falling into the pitfalls commonly associated with discussions of this kind, he steers clear of the pseudo-dialectics which characterized the Soviet debates after 1956. He is well acquainted with the Western literature on the subject, he is not above acknowledging his own past errors, and he is not afraid to engage in controversy. Altogether Brus's book must be considered an important contribution to our knowledge of the working of the socialist economy and as such it well deserves to be translated into English.

Business Fluctuations

Business and Economic Forecasting. By MILTON H. SPENCER, COLIN G. CLARK, AND PETER W. HOGUET. Homewood: Richard D. Irwin, Inc., 1961. Pp. xii, 412. \$7.95.

This is a book "... designed to meet the needs of students, consultants and professional researchers who are interested in the related areas of forecasting and model building." The authors are almost exclusively concerned with the construction of regression models and the use of such estimated models to make forecasts. The only method explained of estimating the unknown parameters of regression models is the graphical method so that anybody with a knowledge of high school arithmetic can understand the mathematical aspects of this book. This desire of the authors to expound a highly technical subject in simple terms causes the book to be much longer than would otherwise be necessary and probably decreases the usefulness of the book to consultants and professional researchers.

Part I (90 pages) discusses forecasting methods, materials and tools. It also includes a twelve-page appendix on the use of logarithms. Various methods of forecasting such as naïve methods, leading series, and sample-surveys are briefly discussed but rejected in favor of the regression method of forecasting. The graphical method of estimating the parameters of multiple regression models is also explained.

Part II (268 pages) presents the data and the estimated regression equations for the following variables: prices (farm commodity prices, prices of raw materials and semimanufactured goods, metals, fuels, interest rates and common stock prices); sales of consumers' nondurable goods (gasoline, beer,

and women's outerwear); sales of capital goods (electrical equipment, machine tools, and oil-well drilling bits); and sales of construction materials (plywood, Portland cement, iron products, steel products, and plumbing fixtures). No attempt is made to evaluate how well these models forecast, indeed no forecasts are made, but rather a graphic comparison of the estimated model and the actual model for the observation period is given. It should be pointed out that the models presented are for expository purposes but my complaint is that they shed little light on the topic of forecasting although they do illustrate some of the principles of model construction.

Part III (37 pages) presents a simple, but lucid, discussion of multi-equation (simultaneous and recursive) regression models and illustrates the topic with a comparison between the Klein-Goldberger model and the Econometric Institute model of the United States. This part might prove useful as an introduction to the topic of multi-equation models in an econometrics course.

The major defect of this book stems from the desire of the authors to hold the level of discourse at a very elementary level. This means that approximately only one page is devoted to a discussion of the essentially stochastic nature of regression models. This in turn means that the sampling variation inherent in such models and in forecasts from such models is not discussed, even to the extent of presenting estimated variances of the estimated parameters. This lack of emphasis on the stochastic nature of regression models also makes it difficult for the authors to present criteria by which one can decide whether a forecast is "good" or not. They seem to regard the ability of a model to predict a change in direction (a turning point) as of primary importance while, in fact, one can easily construct reasonable examples where one would prefer a model which predicts no turning points to one which predicts all turning points.

If this book is regarded as an elementary exposition of regression model construction and of many interesting estimated models then I would give it a high grade, but as a book on forecasting it is somewhat less satisfactory.

JOHN W. HOOPER

Cowles Foundation for Research in Economics
Yale University

Economic Fluctuations and Forecasting. By EDWARD J. CHAMBERS. Englewood Cliffs: Prentice-Hall, 1961. Pp. xv, 649. \$7.50.

This is a well-organized, clearly written textbook dealing with economic changes and their impact on growth, stabilization and price stability in Western countries. Empirical and theoretical work of recent years has provided some new insights into the interrelationships between the three goals of national policy and is a principal reason for the book. In an environment of notable structural and institutional changes, the focus of interest lies in the nature of these developments and their implications for public policy. A section on forecasting is included because successful programs for stabilization or growth stimulation depend largely on accurate assessments and projections.

The organization of the book is almost identical with that of the 5th edition of Bratt's *Business Cycles and Forecasting*. Part I includes a description

and analysis of fluctuations—secular, cyclical and seasonal. Part II is a highly condensed version of U.S. business cycle history since the First World War. Part III is concerned with the theory of business fluctuations, based on the income-expenditure approach of Wicksell-Robertson-Keynes. Part IV discusses aggregative economic forecasting in very general terms; and finally, Part V investigates public policies, in the light of existing complexities and conflicts. Two short appendices on Social Accounting and Business Indicators follow.

Compared with the empiricism of Bratt, the present book is far more theoretical and eclectic. It would appear to have been written for upper classmen and first-year graduate students. The author is scholarly and careful, refusing to take a stance on many economic questions. For example:

To take either extreme position, that is, that cyclical fluctuations represent purely random or outside disturbances or, alternatively, that the oscillation of aggregate economic activity is self-perpetuating, occasioned by the peculiar structure of our business system, is unrealistic (p. 301). The precise way in which decisions are reached is still a mystery. Presumably, however, there is a balancing of pros and cons based upon relevant past experiences, the current situation and expectations (p.297).

An affinity for the approach of the National Bureau of Economic Research is revealed, attested by extensive quotations in support of various propositions (e.g., Arthur Burns is referred to 22 times). Yet, there is a curious lack of quantitative material—the book dwells on description and theoretical discussion touching only lightly on empirical analysis and techniques.

The sections on policy reflect the author's conservative political philosophy:

A program that respects the traditional but not inflexible boundaries between the Federal and State governments is fully in consonance with American political institutions. A program that is an excuse for increasing the centralization of political power is not (p. 416).

The author's style and content suggest that he has read widely, understands his material thoroughly, summarizes and relates it clearly, but that he has done a limited amount of individual analytical or forecasting research. He doesn't appear to appreciate the problems of forecasters—overlooking not only the problems of extensive data lags but the unreliability of preliminary estimates (particularly in some strategic areas such as business inventories). He certainly underplays the role of bank credit flowing to and from the stock market, affecting business turning points. He offers standard prescriptions for dealing with difficult problems, including the usual wage-limited-to-productivity-increase method of dealing with "cost-push" inflation, when those working in the field know the great difficulties in measuring productivity, and estimating the contribution of nonlabor inputs.

A process of selecting and summarizing what has already been written is useful but sometimes offers few operational principles of policy. Does the author realize the role of forecasting errors in the Eisenhower and Kennedy deficits, in connection with the following conclusion?

Whether the institutional changes of the past two decades will require

the invention of new stabilization instruments can be better judged only after we have really tried to harness fiscal-monetary devices in a working relation, for the blunt truth is that we have failed to coordinate them in the postwar period (p. 546).

Does he recognize the operational difficulties as well as possible contradiction with his own political philosophy when he approves John Dunlop's statement that "more leadership by the Federal Government is needed to deal with power blocs"? Surely moral suasion cannot be sufficient.

In my judgment, the strongest part of the book is the history of cycle theory; the weakest is probably the forecasting section (only 12 per cent of the book vs. 32 per cent for Bratt's), which does not fully develop a fundamental concept. While capital investment and consumer intention surveys, and NBER research are handled adequately (though for the latter only eight of the twelve current "leaders" are presented and analyzed), the greatest omission is an orderly development of the standard national income method of forecasting. While superficial treatment of forecasting methodology is consistent with the author's stated purpose, I believe a more complete coverage would have increased the possible uses of the text.

As constituted, it can be used in a business cycle and/or policy course, should a theoretical approach be desired. It is not as useful for a cycle-forecasting course, although it can be supplemented with something like Bassie, *Economic Forecasting*, for amplification of the national income method of forecasting. Actually, a combination of this book with Bratt's and Bassie's provides excellent material for the latter type of course. On balance, the text is a definite contribution, supplementing but not duplicating those already available in the field.

Tufts University

Money, Credit and Banking; Monetary Policy; Consumer Finance; Mortgage Credit

The Postwar Residential Mortgage Market. By SAUL B. KLAMAN. Princeton: Princeton University Press, for National Bureau of Economic Research, 1961. Pp. xv, 301. \$7.50.

This volume is one result of the National Bureau's Studies in Capital Formation and Financing and concentrates on the supply of residential mortgage funds rather than the demand for mortgage funds. Primary emphasis on the supply of funds in the first postwar decade is appropriate to the then-existing environment. With housing demand exceedingly strong, the availability of mortgage funds was more of a determinant of residential construction than it has been in the past two years. Nevertheless, the forces generating mortgage demand even in the first postwar decade merit study if students of the market are to understand more recent and future developments. The author sets as the two major objectives for the volume a description and appraisal of (1) the flow of residential mortgage funds and (2)

the institutional framework of the mortgage market. The volume attempts more than these two broad aims suggest, and the achievements are commendable.

Klaman demonstrates that residential mortgages absorbed more funds than any other single capital market instrument, and in a number of years absorbed more than all other instruments combined. More importantly, his analysis examines in substantial detail the unusually heavy flow of funds into mortgages in the first half of the decade, particularly into federally insured or guaranteed mortgages. Klaman explores the decline of federally backed mortgages in terms of changing capital-market and monetary conditions. The emergence of the conventional loan as an instrument of increased importance and greater stability in volume during the second half of the decade is attributed to its greater yield flexibility. The author might have added that FHA mortgages, unless the borrower needed the more favorable downpayment and maturity terms, actually became a progressively less favorable instrument compared to high-grade conventional loans as FHA contract rates were increased, prepayment penalties were maintained, and processing periods remained rather lengthy. Generally, Klaman's treatment of the changing flow merits approbation. His investigation is objective and thorough and emphasizes the critical variables and policies influencing developments.

Interest-rate developments in the mortgage field are treated comprehensively and with full consideration of market forces and government policies. The author introduces a new series on interest rates for conventional mortgages and a detailed treatment of the relationship among rates on the several different types of mortgages. Some of his points, however, are subject to question. He seems to spend more space on the seeming lag of mortgage yields behind bond yields than the issue merits, particularly since the lag results to a large degree from the fact that mortgage yield data were collected as of the date loans were closed, rather than as of the commitment date. His conclusion that geographic differentials, already reduced substantially in the past quarter-century, cannot be narrowed further because of market imperfections may be too early a surrender. Finally, in evaluating the failure of discounts on FHA and VA mortgages to make them fully competitive with conventional loans, he overlooks the effect of the discounts on the willingness of builders to maintain a given pace of construction.

The most interesting and original parts of the volume for this reviewer are those dealing with policies, practices, and techniques of the various lenders. In each of these areas, the preceding findings are clothed in raiment essential to seeing the market as a functioning instrument. Klaman's treatment of primary and secondary markets is particularly commendable, though one wishes he might have analyzed the recurrent quest for a formal secondary market for conventional loans. The volume also provides a good discussion of junior liens in the postwar decade.

Though the quality of the work is generally high, a few characteristics of the volume merit special comment. The author avoids substantive policy issues. Little is said directly in evaluating the adequacy of the mortgage market or the needs of the periods. Certainly, those who take either side in

the controversy over the adequacy of the supply of mortgage funds in given situations will find that the author has turned his back on this issue. At one point (p. 111) the author raises the question of the wisdom of federal programs in the early postwar years. He concludes that the liberal loan-to-value ratios in VA and FHA loans inevitably contributed to a larger demand for mortgage funds, but the discussion of whether or not the programs were inflationary is left to others. Such issues may have been outside the scope of the author's assignment, but one can regret the absence of their discussion in an otherwise comprehensive volume. The reader may find the summary of findings, in Chapter 1, terse and cryptic. Points made by the author in that section are not cross-referenced to other sections of the volume, and the statements in the summary are difficult to relate, in some cases, to the evidence presented in subsequent chapters.

A few statements, involving verifiable facts, are open to question. Two examples follow: Klamann attributes a lower volume of mortgage acquisitions for savings and loan associations compared with banks or insurance companies in parts of the period to a "reduced inflow of savings" (p. 8). This statement is at least unclear in view of the record of savings and loan associations. Again with reference to savings and loan associations, he attributes a reduced fourth-quarter level of mortgage acquisitions to a seasonal rise in withdrawals (net savings decline) and a need to reduce indebtedness to Federal Home Loan Banks by the end of the year (p. 123). The statistical record supports neither assertion.

Despite these exceptions, the volume is a valuable contribution to capital market literature. Experienced students of the mortgage market will benefit from the assembly in one place of a comprehensive, systematic treatment of the supply side of the market. To the new entrant into this area, it will prove a very useful key to what may be seemingly enigmatic developments. The generalist in the capital markets can turn to the work for illumination of frequently beclouded problems and will find more integration with the capital market in general than the foreword suggests. Finally, while the author does not engage in explicit evaluation of some critical issues, his analysis of the phenomena underlying those issues provides the reader with a base for developing his own assessment.

HARRY S. SCHWARTZ

*Federal Home Loan Bank Board
Washington, D.C.*

The Control of Hire-Purchase. By F. R. OLIVER. London: George Allen and Unwin Ltd., 1961. Pp. 218. 25s.

A respectable number of scholarly books on consumer credit has accumulated by now. Since the pioneer work of E. A. R. Seligmann in 1927, we have had important contributions by Rolf Nugent, by staff members of the National Bureau of Economic Research (culminating in the Haberler study), by Reavis Cox and, finally, we have had the six-volume 1957 study sponsored by the Board of Governors of the Federal Reserve System. The present work, however, is the first major study by a British author, an understand-

ably belated development since consumer instalment credit, or hire-purchase in British terminology, has only recently become truly important in the United Kingdom (and even now is still far short of its relative importance in the United States, especially with respect to new automobile sales).

This study may be thought of as something of a British counterpart of the Haberler study, but it comes a generation later and thus utilizes more recent data, both for the United States and the United Kingdom (although data for the latter has apparently been utterly inadequate until very recently). It is an analytical study, with institutional description held to a minimum; and it moves rapidly from description to a discussion of motives for using hire-purchase and to the economic consequences of consumer credit: for example, the effects on savings and on the supply of and demand for goods. Long-term and short-term behavior of instalment credit, and interrelationships of instalment credit and the business cycle are examined. Next comes an analysis of the presumed gains to be obtained from employment of consumer credit controls. The final chapters deal with United States and British experience in the control of consumer credit, the implications of that experience and the preceding economic analysis, and some observations on the Radcliffe Report.

Although Oliver regards the pro-cyclical behavior of hire-purchase credit as largely caused by the cyclical behavior of income, he nevertheless finds a reciprocal relationship which he makes the basis for a defense of permanent consumer credit controls. He argues that the cyclical impact of consumer credit involves a transfer of demand to durable goods whose production is basically more volatile in character than that of nondurable goods. The effect is compounded by a pipeline lag in the production of such goods with a resultant multiplier effect. Between the dissaving induced by hire-purchase credit at time of purchase and the lag in repayments, Oliver finds a built-in amplifier of the cycle which requires control in the interests of greater economic stability.

Thus the author maintains that "subject to the need to show that controls actually work, there is an economic case for a regular pattern of controls which would serve both to limit booms and to mitigate slumps" (p. 153). He then proceeds to examine the admittedly circumscribed British and United States experiences, which, he holds, demonstrate reasonably well that hire-purchase controls via the mechanism of down-payment and (especially) maturity regulations do work. He concludes therefore that permanent and regular controls on down-payments and maturities are desirable. In this respect he takes issue with the Radcliffe Committee for preferring a very limited role for consumer credit control (and with the Federal Reserve Board of Governors for its opposition to such controls).

This work gives a concise description of the economic problems of consumer credit control. Since it contains and relies on recent United Kingdom data, it should be useful from a British point of view. From the American standpoint, it adds little to our understanding of the problem, mainly because it comes so soon after the recent massive Federal Reserve study. Analytically, it does not add significantly to existing literature and indeed may be viewed primarily as a restatement of the issues.

It is the reviewer's privilege to offer criticisms of a work, and this writer uses his privilege first of all to take issue with the author's neglect of the dynamic role of consumer credit in stimulating economic growth and in helping to transform the character of an economy. There is inadequate reference, in this reviewer's judgment, to the "mix" of monetary-fiscal controls. For example, considerable attention might be given to the relationship between debt management and the behavior of consumer credit. Thus an argument may be made for the use of hire-purchase controls as an instrument to be coordinated with debt management policy. The author might have enlivened his work considerably had he considered the experience of countries other than the United Kingdom and United States. Indeed from some points of view the experience of countries other than the United States would be more relevant to the United Kingdom experience since there is greater similarity between the economies of some of these countries and that of the United Kingdom with respect to the emerging roles of consumer durable goods and consumer credit. In conclusion, although this work serves a useful purpose at this time, a definitive British effort in this field must still be awaited.

ERVIN MILLER

University of Pennsylvania

Bases analíticas de la política monetaria. By BRUNO BROVEDANI. Mexico: Centro de Estudios Monetarios Latinoamericanos, 1961. Pp. 144.

This small volume, another in the series published under the auspices of the Latin American Center for Monetary Studies, sets forth a highly useful analytical framework for dealing with the monetary problems which are more or less peculiar to the world's underdeveloped areas. Based on lectures which the author (an economist with the International Monetary Fund) delivered in 1960 at the Center, the analysis is simple throughout, as perhaps befits a work directed mainly to the needs of Latin America's budding central bank technicians.

The author deals successively with the nature of central and commercial bank data; the system of monetary equations into which such data are fitted; the credit multiplier in both theoretical and empirical terms; Latin America's foreign exchange system; seasonal, cyclical and trend factors; expectations relevant to credit policy; and policy formation per se. Most categories are illustrated, at least briefly, with data from more or less representative Latin American sources; and wherever possible the analysis appropriately emphasizes relevant balance-of-payments features.

On the critical side, this reviewer has only a few doubts to express. Thus, is it correct to state that the quantity equation is useful only in instances in which supply is infinitely elastic and velocity constant? (pp. 15-16). Is this not also an instance of the tendency to overlook distinguished and relevant non-Keynesian analysis? Reference is made chiefly to the work of Arthur Marget. We are also told that the market rate of interest has little effect in limiting the demand for credit under Latin American conditions (p. 60). Is demand really that interest-inelastic, or, putting it differently, are the necessary conditions as generally prevalent as such a statement implies? Regarding Latin America's automatic stabilizers, Brovedani views

official programs for purchasing and selling exportable surpluses as no less stabilizing than, say, the progressive income tax (p. 91). But are these two types truly coordinate? Surely the relative size of the exporting country's shipments, coupled with the official price at which operations are conducted, have a lot to do with the claimed stabilizing role.

Among central bank powers, the discount instrument is regarded as fundamental and primary (p. 124). But if this is the case it is only, or largely, because Latin American nations almost without exception lack a developed capital market and thus the central banks are deprived of the opportunity to employ tools which top the list of powers found in the really advanced countries. This point is of some moment to Brovedani's over-all argument on strictly technical grounds, and in addition is significant relative to the general problem of economic development in that it illustrates an important condition, given other requirements as well, under which numerous, gain-minded economic rationalizers are at work to speed economic growth.

Finally, since monetary policy is but a part of economic public administration, it is a pity that the author failed to emphasize the weak state of public administration south of the Rio Grande and the implications, in terms of the desire for headway under free institutions, for public action by technically capable people in various operating areas, including the monetary.

Public Finance; Fiscal Policy

The Growth of Public Expenditure in the United Kingdom. By ALAN T. PEACOCK AND JACK WISEMAN. Princeton: Princeton University Press, 1961. Pp. xxxi, 213. \$5.00.

The authors of *The Growth of Public Expenditure in the United Kingdom* have produced an interesting and informative study but one whose title is somewhat misleading. The book does include data on expenditure growth, but its primary purpose seems to be the testing of certain hypotheses about the reasons for such growth and the time pattern it exhibits. However, there are plenty of statistics for those whose interest is primarily quantitative.

The authors attempt to develop a general theory to explain for this century why sudden jumps in peacetime expenditures have followed periods of war, while rate of growth in interwar periods has been relatively low and stable.

The reader who is in a hurry or impatient with columns of figures can profitably confine himself to the exceptionally well-written Introduction and Summary. In this section, the important concepts are defined and their derivation explained, and they are then woven into a theory of public expenditure growth, or, more accurately, a theory explaining why public expenditures grow by fits and starts.

The authors argue that wars produce "displacement effects," i.e., upward shifts in the levels of both revenues and expenditures which persist after the wars are over. Tax burdens which would not have been tolerated prewar are shouldered more or less willingly during wars, and this willingness carries

over into postwar periods. Along with this, there is a greater postwar demand for public spending. Part of this demand is already latently present in the sense that more government spending has been desired all along but could not take place because of resistance to higher taxes during peace. Partly, however, increased demand results from an "inspection process," a war-induced awareness of social needs and of membership in the broader public community.

Accompanying the displacement effect, or more accurately a part of it, is a "concentration process." This refers to the fact that an increasing share of public expenditures are accounted for by the central government following periods of war. This comes about partly due to the allegedly superior efficiency of centralized administration but partly because of a war-induced or heightened desire for uniform levels of public benefits and services.

The most convincing part of the argument is that which concerns the effect of war on the willingness of the community to support permanently higher levels of taxation. The importance attributed by the authors to the inspection effect as an explanation of increased spending seems exaggerated to the reviewer, though the argument for the existence of such an influence is quite convincing. Least satisfactory is the explanation of the concentration process, though the fact of increasing concentration is not itself disputed. The reviewer feels that concentration is much less the result of the existence of realizable technological efficiencies or of community-wide desire for equality than it is of the fact that the revenues of the central government increase more rapidly during the war than do those of local governments. In other words, the central government spends more because it has more to spend. But my objections are not serious ones. The authors make a convincing case for the existence and importance of their various "processes" and "effects" and are probably all too well aware of the difficulty of assigning weights to them.

A final, though again not serious, criticism of the conceptual framework is that more stress could have been put on the historically relative character of these concepts. The authors show quite clearly that the behavior of public expenditures was different in the period preceding the one they examine (1890-1955), and they should perhaps have more clearly taken into account the possibility that the displacement effect may run into diminishing returns in the future—assuming there are any taxpayers left after another war.

As for statistics, they are plentiful and impressive, though the amount of estimation involved in making data comparable over time is always somewhat appalling to those not overly statistically minded. No matter how sophisticated the supporting arguments, some (the reviewer among them) are left with a feeling of unease when statistical series are advanced as substantial evidence of the validity of various theses. In this connection, however, Peacock and Wiseman are commendably cautious. They claim only that the statistics they cite are compatible with, rather than conclusive support for, hypotheses which are convincing on other as well as on statistical grounds.

The Role of Debt in the Economy. By HELEN J. COOKE. Washington: Public Affairs Press, 1961. Pp. ix, 115. \$3.25.

Economists who venture forth among laymen find that, sooner or later, they must face up to some questions about debt. More often than not, when this occurs, they must also endure the discomfort that arises from squirming through tangled notions of morality, monetary crankisms, and plain bad information. To all who have plumbed these depths, Dr. Cooke's study will come as a pleasant and useful tonic.

This little book examines succinctly the central points at which the institutions of our credit system touch the performance of our economy. It explores the rationale of our debt system by looking at the reasons why borrowers find debt convenient, expedient, or economical, and the reasons why lenders find debt profitable.

A chapter on "The Debt Structure" is focused on the relative share of debt owed by the major borrower sectors and an evaluation of "the burden" of debt for each sector. For most sectors the author records the major changes since 1929 in debt patterns: types of securities, purpose in borrowing, and financial position ratios. Discussions of the burden of debt, which focus primarily on the relationship between debt service requirements and income, support some conclusions that are reassuring:

Corporate debt: "This burden is still relatively low . . ." (p. 26)

Consumers debt: ". . . does not appear to be unduly burdensome." (p. 31)

Farmers debt: ". . . the current burden does not appear to be excessive. . . ." (p. 37)

Non-corporate business debt: ". . . the burden . . . and the danger of default is likely to be greater for small business as a whole than for large or corporate business." (p. 41)

Federal debt: "The interest payments seem to be well within the ability of 'the borrower' to carry." (p. 45)

State and local debt: "The current overall interest burden does not appear to be high." (p. 51)

The chapter "Debt and the Lenders" briefly covers the institutionalized portion of the supply side of the money and capital market. Its content is a capsule of what one can find in the descriptive sections of the traditional money and banking text. There is an elementary discussion of the Federal Reserve System with a focus on Federal Reserve history and law. Lending policies of commercial banks, insurance companies, savings and loan associations, and other financial institutions are examined with reference to liquidity and solvency needs and government regulation and support.

The book ends with two short sections on "debt and economic fluctuations" and "the outlook for debt" which convey sensibly what the author intends: that debts will continue to grow with the rest of the economy and, from time to time, will foster instability.

This book is, admittedly, an introduction to the subject. Its 98 pages of text are shorn of theoretical structure beyond the truism: for every borrower, there must be a lender. Yet, for the student who has not read a money and banking textbook, it will create an awareness of the omnipresence of debt

and the consequences of operating an economic system with debt as a part of its institutional structure.

In the introduction, which is written by W. H. Steiner, discussion of such topics as the Gurley-Shaw thesis are explicitly ruled out of the book as controversial. Why Gurley-Shaw was interdicted when other controversial issues, such as the federal debt ceiling (about which Professor Cooke has written elsewhere) and theories of treasury debt management policy, were included, is not clear. It is regrettable, because I suspect that if the author had taken into account the advances that Gurley and Shaw have made in monetary theory, the "role" of debt would have emerged much more clearly; more controversial perhaps, but also more systematic.

The only major defect in the book is its inadequate treatment of one of the potentially important problems confronting societies that rely on a private credit system: the problem of mass and cumulative liquidation. Those who have not otherwise been informed of the characteristics of financial panic or of the progressive liquidation of debt that can occur in a pyramided private credit structure will not have that lacuna filled here. For an introduction to the role of debt, this is an unfortunate oversight. We have invented a number of structural safeguards since the early 1930's; but, until they are tested, the spectre of financial crisis cannot be dismissed in a serious examination of our financial structure.

Nevertheless, Mrs. Cooke has done an able job for which we can be grateful. She has shown the reader that debt is an economic institution which can be examined in a systematic way without reference to moral or political issues. I hope many people will read it.

MARSHALL A. ROBINSON

University of Pittsburgh

United States Fiscal Policy 1945-1959: Its Contribution to Economic Stability. By A. E. HOLMANS. New York: Oxford University Press, 1961. Pp. xiv, 342. \$6.40.

Holmans presents a detailed narrative of fiscal policy-making in the post-war era, stressing the relation to economic stabilization. He opens with an excellent summary of the institutional setting of U.S. fiscal policy, with its fragmentation of tax and appropriations responsibility. Then follows a penetrating analysis of the ideological overtones prominent in fiscal debate. Countercyclical finance is attacked by conservatives in the United States, he notes, because of fear of irresponsible extension of government power, while by contrast, in Europe it has been recognized as a conservative alternative to more extreme government intervention.

The chronological narrative itself is uneven in quality. At times the amount of irrelevant detail seems excessive, and the reader loses his way. There are tangles of proposals and counterproposals, with the reasoning behind each. But on balance, the narrative of policy actions contains much of value. If read judiciously, it conveys well the great variety of factors which influence fiscal decisions—pressure-group concern with particular tax or expenditure programs, balanced-budget ideology, practical considerations of appropriate

government influence on the flow of expenditures, the inescapable problems of national security, and the infighting of partisan politics.

There are abundant and frequently colorful quotations from Congressional hearings and debates, from presidential messages, and from the press. We learn, for example, from one senator that deficit spending is bad because "it leaves out the human equation and the spiritual drives that are our greatest resource" (p. 239).

Holmans concludes that postwar fiscal policy was reasonably successful, and that while this was partly a matter of luck, "capable management of national economic policy was never a negligible factor" (p. xiii). He is impressed by the absence of destabilizing actions such as recession-inspired economy drives, and credits this in part to "a steady increase in familiarity of men in public life with the elements of counter-cyclical fiscal policy" (p. 298).

He is impressed by the restraint shown in adopting expansionary measures during recessions, contrasting it with the oft-expressed fears of fiscal irresponsibility. At the same time, he is confident that "more drastic measures would have been taken had the recessions proved more severe or prolonged" (p. 299). True, the balanced-budget doctrine has wide vocal support. But "when deflation is the pressing problem, the balanced budget has to yield to the more urgent goal of checking the decline and bringing about recovery, both out of common humanity . . . and to avoid the fate that the recent historical record suggests awaits parties that allow serious recessions to develop" (p. 302).

His optimistic views do not prevent Holmans from suggesting that improved flexibility may be needed. He expresses concern over the recent unwillingness to use tax-rate changes countercyclically, and over the tardiness with which both the Truman and Eisenhower administrations were willing to recognize the existence of recessions.

Although the conclusions are defensible, some readers will find the actual analysis of year-by-year consequences of fiscal policies superficial. The book can usefully be supplemented by the more incisive, though perhaps overly critical, Joint Economic Committee Staff Report on Employment, Growth, and Price Levels. Nevertheless, Holmans' book constitutes a valuable contribution to the literature of political economy.

PAUL B. TRESCOTT

Kenyon College

Finanza pubblica. Vol. I. By LELLO GANGEMI. Naples: Giannini, 1961. Pp. xii, 470. L. 6,000.

This book is the first of two volumes of Professor Gangemi's work designed as a university textbook in public finance. In fact, the two volumes represent the sixth edition of the author's *Elementi di Scienze delle Finanze* with the basic difference that the latest edition aims at presenting a "system."

The reader soon discovers that one of the most noteworthy features of the volume under review is its cosmopolitan character, which finds expression in both the presentation of public finance theory (without institutional links)

and the extensive international bibliography. While it is difficult to estimate the benefit reaped by Italian students from Gangemi's international scholarship, it seems that the author has struck a compromise at the expense of his country's fiscal policies and problems. Due to the very limited attention given to them, the book will be found much more normative than positive. This plus the fact that statistical data or illustrations are largely absent may be considered the book's serious deficiency. How is the student to acquire some sense of proportion among the monetary and other quantitative magnitudes which are inseparable from the collection and disbursement of the taxpayer's money by his government?

The book concentrates on the general aspects of a public economy (devoting as many as 50 pages to the "sociological" ones), and on public expenditures and public revenues obtained through taxation. In all these respects, it is highly didactic, very comprehensive and carefully organized. Should the second volume maintain the level of the present book, it will be a valuable contribution to the literature on the distributive effects of taxation, public debt and fiscal inflation, functional finance in both developed and underdeveloped countries, social security, and the finance of the European Common Market.

From Gangemi's point of view, public finance is a very complex science as his own definition suggests. In terms of the latter, public finance is a discipline which studies all: the causes; the economic, technical and juridical methods; and the economic and social effects of the compulsory action inherent in collecting government revenue. It also studies the use of the means that enable public bodies to perform their functions which are qualitatively and quantitatively determined by the holders of governmental power operating in different countries within the framework of different political and social structures (p. 15). But the basic difficulty in arriving at a financial organization capable of realizing the principles of financial rationality and justice is, in Gangemi's conception, explained by the close relationship between public finance on the one hand and sociology, social psychology and law on the other hand. Unavoidably, having looked for complicated relationships, the author finds a complicated reality—and justly so. As may be expected of Continental economists trained in law schools, Gangemi contends that what determines the scope of governmental "financial sovereignty" is the existing law.

Also in line with European tradition is the view, adhered to throughout the book, that the State is a factor of production, an agent of social cohesion, with definite objectives to fulfill, which need not be in harmony with the aims of the economy. In the free economies this rather common fact can hardly have a disturbing influence if one postulates or takes for granted, as one does on the Continent, that present-day national governments implement welfare states. Gangemi leaves no doubt about his belief in the *stato sociale moderno*.

Despite the fact that by far the largest portion of the author's fiscal theory applies to Western democracies (*area euroamericana*), he gives some abstract attention to totalitarian financial systems, but fails to produce any analysis

worthy of special note. Neither are nationalization and problems connected with it accorded the desirable analytical interpretation.

It is quite natural for Gangemi to incorporate in his system many ideas of other, in most instances Italian, public finance experts. From among these, DeViti's theory of transportation rates may be briefly referred to (pp. 307-8). These rates have two developmental stages: in the first, they diversify and multiply, and in the second, they show a tendency toward simplification and unification. The more people use a particular transportation facility, the greater the tendency toward a general, average, but gradually proportional rate which does not directly differentiate between travelers for short or longer distances. The transportation company need not set its rates; it merely accepts those rates which arise from the above process. The latter is, moreover, supplemented by the tendency of rates to become lower in response to increased consumption, i.e., due to the economies of large-scale production. Through such a process of rate unification one arrives at a subscription price (e.g. a weekly railroad ticket) which, in DeViti's view, becomes the incidence of income taxes imposed on the seller (public utility company). Gangemi accepts the theory, but without examples.

It appears that practically all Italian writers in the field of public finance have been critical of progressive tax rates. This author, too, is conscious of the fact that progression is unsuitable for countries with relatively low per capita incomes and the income distribution peculiar to them (pp. 386-96). (Nevertheless, there are progressive tax rates in the Italian tax system.) His analysis of the six types of progression detectable through international comparisons, with accompanying graphs, is useful. Gangemi lists altogether ten arguments against progression and asserts that these tax rates are in conflict with decreasing marginal utility of higher incomes and, particularly, the steadily rising cost at which they are acquired. Once more he agrees with DeViti that progression is best adaptable to the taxation of inherited wealth.

In this first volume of his system, Gangemi has in many respects accomplished what he set out to do. Because of its exhaustive coverage of theoretical principles, the book deserves international attention.

Boston University

International Economics

Foreign Trade Credits and Exchange Reserves—A Contribution to the Theory of International Capital Movements. By BENT HANSEN. Amsterdam: North-Holland Publishing Co., 1961. Pp. x, 144. \$3.80.

This is a pioneering effort to explore theoretically, and to a limited degree empirically, the recondite subject of the financing of foreign trade, and to relate changes in trade credits to changes in the balance of payments on the one hand and foreign exchange reserves on the other. It appears at an opportune time since interest in short-term capital movements has revived; and it was in fact inspired by substantial changes in the Swedish balance of

payments on current account in 1955 to 1958 which, in the absence of visible capital movements, were thought to reflect changes in trade credits, or what are called in Britain and the United States, the "leads and lags."

The analysis, as one expects from Hansen, is rigorous and acute. Starting off with definitions and a discussion of the difficulties of measuring trade capital from the residual in the balance of payments, he proceeds to demonstrate through algebra how trade credits—representing the difference between deliveries of goods and payments for them (positive or negative) are affected by changes in a wide number of variables—the price and quantity of goods traded, the credit period, interest rates at home and abroad, and the spot and forward rates of exchange. The major finding throws some doubt on the accepted view that a rise in the domestic interest rate will increase the import (or reduce the export) of trade capital. This is true of deferred payments (when delivery precedes payment). With higher interest rates at home, foreign bills will be discounted more quickly; and the effect of rising interest charges in reducing the volume of exports will work in the same direction. But on prepayments, the effects operate in different directions: higher interest rates at home lead to a demand for more prepayments and longer credit periods, but higher costs reduce exports and tend to reduce the import of trade capital. One surprising empirical finding, which increases the significance of this theoretical result, is the large size of advance payments to Swedish exporters. At the end of 1957, advance payments on exports amounted to almost 1 billion Sw.kr. compared with annual Swedish exports of 11 billion in 1957 (p. 120).

The analytical subtlety which Hansen brings to bear on the problem is put into some question when he describes how Swedish traders and commercial banks actually operate. For example, he states (p. 73) that Swedish banks discount foreign bills at their domestic discount rate even when the foreign discount rate is lower, which suggests irrationality or barriers to competition on the part of the exporters who could get a higher return by developing banking connections in London; and again (pp. 73, 74) Stockholm banks discount foreign (sterling) bills at the spot rate of exchange and almost always hold them to maturity, thus embracing the exchange risk, whereas in his analysis banks and traders speculate only when they expect the future spot rate to depart from today's forward rate, and for the most part remained hedged. The finding that Sweden finances its exports and lets foreigners finance Swedish imports, on balance (p. 121), also and admittedly raises doubt as to the value of pursuing to the last subtlety analysis which supposes that interest-rate differences are dominant.

Finally, one may question whether Hansen divides his time properly between the problems arising from changes in exports, imports, credit periods, interest rates, and expectations with traders avoiding exchange risks, and the interesting and trying case where traders speculate. The latter is dealt with neatly and correctly but in only two pages (pp. 105, 106). It would have been useful to have Hansen's views on the relative importance of swings in trade credits based on trader speculation, and those arising from the other

monetary and commercial considerations with which he deals, especially in the light of the wide swings in "leads and lags" in the British balance of payments, and perhaps recently in the United States.

Despite these qualifications, the monograph is an interesting and important contribution on a relatively unexplored subject in which analytical elegance is on the whole combined with, rather than substituted for, relevance.

C. P. KINDLEBERGER

Massachusetts Institute of Technology

Economic Integration: Aspects and Problems. By PAUL STREETEN. Leyden: A. W. Sythoff, 1961. Pp. 150. f 12.

Streeten has written a collection of essays which deals with some of the most important aspects of the rather broad subject of economic integration. The first three chapters deal rather closely with the subject of European integration. Chapter 4 is an essay on the pros and cons of domestic vs. foreign investment, while Chapter 5 contains a most interesting essay on the subject of unbalanced growth. In the first three chapters, economic integration is used in the sense of bringing together a number of countries in a community of nations in which, from the economic viewpoint, the significance of national boundaries has been reduced to a minimum. In Chapter 5 economic integration is used to express the degree to which economic progress on different fronts and at different times should be coordinated or "balanced."

Chapter 1 briefly surveys postwar attempts at European integration, including proposals for a regional customs union, EPU, Schumann Plan, etc., and contains a comparison of the Common Market and the European Free Trade Area. In discussing the Common Market, the point is made that the European Economic Community (EEC) has so far acted liberally and that there were forces present which might well push both the EEC and EFTA in the direction of an Atlantic Economic Community, including the United States and Canada, which would move toward non-Soviet world free trade. Streeten's observations are particularly interesting in the light of the subsequent foreign trade proposals by the U.S. Administration.

The case for European free trade and free factor movements is considered in Chapter 2. On balance European integration is seen as having net foreign trade advantages, although disadvantages are also indicated by the author, such as the disrupting of trade relations with non-European countries, like the British Commonwealth. Streeten expresses doubts with regard to the classical arguments for free trade, finding it questionable whether free trade is a sufficient condition for bringing about the desirable reallocation of resources and then noting that, even if it did, European free trade is only a regional and partial scheme; which necessarily implies that it would lead to some misallocations which have to be set against the improvement. As for free factor movement, the point is well made that the gains are likely to be greater and more certain if they are accompanied by common European policies relating to investments, the balance of payments, and employment. In the absence of such policies Streeten believes that restrictions on factor movements may give better results. The reviewer would hope that this is not

taken to mean that the actual freeing of factor movements should await the adoption and implementation of such European policies. For reasons very similar to those argued by the author with respect to unbalanced growth, the freeing of factor movements in advance of agreement on common policies may lead to common policies, whereas insistence on a simultaneous approach may lead to neither.

Streeten devotes his third chapter to the objections which have been made to European free trade. He sees the inevitable dislocation as a necessary condition of improved allocation, although it must be counted as a cost of the desired benefits. He recognizes that free trade makes less rapidly innovating countries vulnerable, but feels that this can be offset by the spreading of innovation. He is concerned with what would happen to the British Commonwealth, but seems to feel that this could be handled by allowing the underdeveloped Commonwealth countries to join on the same terms as the associated overseas countries, namely, permitting them to protect their infant industries with a preferential tariff on European goods, while their products are granted free access to the whole European market.

Streeten is also concerned with the balance-of-payments implications of European integration. He takes for granted the need for realignment of exchange rates if European integration takes place (a proposition with which the reviewer does not agree) but after integration regards devaluations or floating exchange rates as frustrating the very purposes of integration. Nevertheless, he sees the persistence of balance-of-payments problems. As with others, his remedies lie in the direction of advocating more liquid reserves or credits. He seems to see in import restrictions one technique for coping with balance-of-payments difficulties, and in general reflects a greater willingness to use this device than the reviewer would think warranted. On the other hand he recognizes that import restrictions by themselves do not contribute very much to the solution of dynamic disequilibria and indeed might aggravate them. He points to the possibility of a common currency and full monetary integration. He suggests some sort of use of a European central bank which would grant credits linked with a scheme to make loans to underdeveloped regions. His discussion of regional balance-of-payments problems is stimulating but leaves one unsatisfied because he does not put the European currency problem in the context of worldwide convertibility and existing international institutions.

Chapters 4 and 5 are separate essays although they have implications for European integration. Chapter 4 deals with the cost and benefits of domestic as against foreign investments. Streeten focuses on whether private decisions guided by profit considerations coincide in this field with the national economic interest. He feels that whether countries should, from a national viewpoint, discourage capital exports and encourage imports of capital, would depend on the relation between the divergence of private profits and national gains at home and abroad. Streeten makes the very useful point that capital-output ratios are not constant for increments in investment and that it is impossible to derive the capital-output ratio for a specific foreign project from prevailing capital-output ratios in a foreign country. Unfortunately, in some

countries planning (incidentally, on the advice of foreign expert economists) is based on the erroneous assumption of a constant capital-output ratio.

He seems to be convinced that foreign private investment is unstable and requires frequent adjustments in the balance of payments of the receiving countries. From experience, it is the reviewer's opinion that changes in foreign private investment do not seem to have been a major cause of the repeated balance-of-payments crises which many of the underdeveloped countries have experienced in the postwar period. Streeten, of course, recognizes the constructive use that can be made from inflows of private capital.

The final essay gives Streeten's views on balanced versus unbalanced growth. Streeten joins the other more realistic economists who recognize that growth is inherently unbalanced. The burden of Streeten's theme is "that in certain conditions unbalance may stimulate rather than impair progress, that it may be a condition of, rather than an obstacle to, rapid growth, and that too great an emphasis on balance may cause, rather than prevent stagnation. Bottlenecks may not only, in some conditions, hold back production, but they may also, in other conditions, powerfully stimulate the growth of the complementary activity that has lagged behind" (p. 102). Among his principal arguments are: that complementarity can support the argument for unbalance as well as balance; that in dynamic society new wants are created in the process of satisfying existing ones and complex consumption patterns spring from simple innovations; and that unbalance leads to new consumption opportunities which in turn lead to new investment opportunities. In this essay on growth there is virtually no discussion of economic integration as such but there is the point that in a large economy the benefits of unbalanced growth can be more easily combined with those of balanced growth. This is one of the key advantages offered by the Common Market.

In this volume Streeten has served an appetizing hors d'oeuvre, but the main courses are still to come. In a larger volume he might explain more about what government policies he would advocate to deal with the various problems set forth, give more attention to problems of monetary policy including balance-of-payments and exchange-rate policies, expound more on the differences in conditions found in various countries, and, generally speaking, give more evidence for the validity of his point of view. However, even in these brief essays, Streeten has provided much food for thought and alerted his reader to possibilities that might otherwise be neglected.

IRVING S. FRIEDMAN

International Monetary Fund

The Theory of Economic Integration. By BELA BALASSA. Homewood, Ill.: Richard D. Irwin, 1961. Pp. xiii, 304. \$5.50.

During the years of negotiation and compromise which led to creation of the European Common Market, a large body of theoretical and empirical literature accumulated on the economic effects of regional integration. The apparent success of European measures of integration, and the appearance of several other schemes for regional integration, have stimulated even more studies in recent years. Balassa surveys this large and growing body of litera-

ture in the present volume. He regards the theory of economic integration as a part of international economics, but in his survey he finds it necessary to deal with a wide variety of material. As with international economics, it is necessary in discussing economic integration to make use of analytical methods and data developed in nearly all branches of economics. Thus, in less than 300 pages of text Balassa discusses an enormous literature, touching on welfare economics, growth theory, monetary and fiscal policies, economies of scale, several topics in international economics, and also examining the growing literature on regional economics. He covers not only theory and related empirical results, but also includes brief accounts of institutional and descriptive aspects of the EEC, EFTA, and Latin American common markets. Of these, the EEC is by far the most thoroughly covered.

On the whole, Balassa has succeeded extremely well. His discussions are balanced, clear, and well-organized. However, space limitations sometimes require him to be almost painfully concise, as when he summarizes the factor-price equalization discussion in just three pages. In many places his discussion consists of a succession of one-sentence summaries of pertinent articles and monographs. It is significant that the book does not contain a single diagram or equation—this in a field in which both devices flourish. As a result, although this book provides a useful over-all view of the subject and an excellent guide to the literature, for anything like a full understanding one must go to the literature that has been summarized. One particular virtue of this book is that much European literature, relatively unfamiliar to U.S. readers, is included in its purview.

The book is divided into three parts: statics, dynamics, and policy. In Part I, Balassa deftly summarizes the now familiar analysis of a customs union under static assumptions. He believes that reallocation of production in Europe will result in more gains than most writers have thought, but he is cautious about the welfare effects of the EEC. He concludes with a "guess" that under static assumptions *world* welfare will decline, largely because the marginal utility of income is higher in underdeveloped than in advanced countries. This part of the book also contains a chapter in which factor movements receive more attention than in most discussions of customs unions.

Part II, dynamics, is largely concerned with the influence of market size on growth and productivity, and with internal and external economies. Here the limitations of space do not press so heavily, and the exposition is richer and more complete. Balassa examines a variety of empirical studies bearing on the theories presented, and even undertakes to test hypotheses. The tests are a bit forced, but in this part of the book Balassa makes a real contribution. He is considerably more optimistic about the potential economic gains to be achieved through integration than most other writers have been. He concludes that expansion of the market through integration will make possible significant improvements in productivity, mainly because of the beneficent influence of internal and external economies. He thinks such economies will be important in both European and Latin American integration, but in several places he argues that potential gains are especially important in unions of underdeveloped countries. Empirical studies are assembled, analyzed, and

found to support these conclusions. (Here, as elsewhere, Balassa relies on existing empirical studies. He has made none himself, although his analysis of existing studies is valuable in itself.) Other dynamic factors, such as the effect of integration on market structure, degree of competition, rate of technological change, and rate of investment, are more briefly treated.

Balassa clearly regards the dynamic aspects of integration as more important than the static, although he tries to marry the two in his chief criterion for success of an economic union, namely, its ability to achieve "dynamic efficiency." This term is defined as "the hypothetical growth rate of national income achievable with given resource use and saving ratio" (p. 13). Although he is optimistic about the dynamic gains that may accrue to the members of an economic union, he is less certain about the effect on third countries. In the EEC, growth effects may outweigh harmful trade-diversion and terms-of-trade effects in a twenty-year period, but in Latin America the outcome is uncertain because prospective structural changes make it difficult to know with what alternative situation one should compare economic integration.

Part III, policy, deals with the problems of coordinating or harmonizing social legislation and monetary-fiscal policies in a customs union. It also contains interesting sections on balance-of-payments and intraregional growth problems of a union. Balassa analyzes each of several different policies in order to determine whether or not harmonization is desirable from the standpoint of economic efficiency. This is a valuable and often ingenious discussion of problems that have not figured prominently in economic writings on regional integration. However, the results cannot easily be summarized. In general, Balassa opposes harmonization where national differences reflect basic differences in competitive costs. Such differences should be removed by competition in product and factor markets. But where differences in social policies mask or even distort competitive cost structures, Balassa favors harmonization.

Considering the limitations of space, Balassa has packed a remarkable amount of theoretical and empirical analysis into this book. It is the best all-around survey of the subject I have seen.

The European Common Market—An Analysis of Commercial Policy. By ISAAH FRANK. New York: Frederick A. Praeger, 1961. Pp. 301. \$8.50.

Books on European economic union are coming at flood rate. This is a good one, limited in scope, carefully documented, sprinkled with good judgments. The author, in charge of the Office of International Financial and Development Affairs in the Department of State, writes from a background of solid experience and close attachment to the issues involved; yet he treats his problem with a sufficiently broad perspective so that the average reader will not get lost in the trees.

The work is sensibly organized. The first chapter provides a brief survey of the problem of European economic union in the early 1950's, in the in-

stitutional context of the existence of the OEEC and GATT. Chapters 2 and 3 deal with the Rome Treaty's handling of tariffs, quotas, and discrimination among the Inner Six. For the most part these chapters deal with technical problems, but Frank emphasizes the issues involved, not the details. Toward the end of Chapter 3 an attempt is made to assess the economic effects of the union, but this is not very satisfactory, going little further than discussion of Viner, and Meade's extensions of Viner's analysis.

Relations of the Common Market countries to the outside world in general are treated in Chapter 4, with emphasis on the basic issue of the height of the common external tariff. While in this discussion and elsewhere Frank recognizes some of the limitations of the usual measures, drawing extensively on Viner's well-known cautions developed in 1936, nowhere does he deal directly with the importance of an *ad valorem* rate on value added, as contrasted to total value, in measuring the degree of protection afforded by tariffs. This is a shame, because at least in this reviewer's opinion it is a relevant and indeed probably essential element of the problem.

An interesting summary of most of the basic commercial policy issues involved in obtaining agreement between the Inner Six and the Outer Seven is provided in Chapter 5, followed by a long chapter on quota problems of the Community. This last chapter is the only attempt Frank makes to go deeply into an issue, and presumably is in the nature of an appendix. In it he makes a persuasive case that quotas cannot be applied effectively against the outside world by Common Market countries to correct balance-of-payments difficulties without disrupting free trade within the Community, and that therefore more intensive efforts must be made to strengthen Community influence over national monetary-fiscal policies of individual members.

This reviewer is glad that a man of Frank's ability and judgment, as shown by this unfortunately grossly overpriced book, is representing this country in commercial policy negotiations with Europe. We are in good hands.

Haverford College

The Dollar in Crisis. Edited by SEYMOUR E. HARRIS. New York and Burlingame: Harcourt, Brace and World, Inc., 1961. Pp. x, 309. \$3.45.

Despite the use of the singular case in its title, this book is about two "crises," the dollar glut and the alleged shortage of international liquidity, even though most of the fourteen pieces—prefaced by an introductory essay longer than any of the contributions, from S. E. Harris' experienced editorial hand—concern themselves with causes and cures of the recent U.S. balance-of-payments deficits. The two problems are distinct, the cure of either one does not mitigate the other. Even though they are of course interconnected by the fact that the U.S. dollar is the chief reserve currency, they require separate diagnostic and remedial treatment, and the book does not gain from putting two severely debated but separate issues between the same covers.

There is little disagreement among the contributors about the basic diagnosis of the U.S. balance of payments. (1) It has recently shown an abnormally large deficit, caused in the end largely by short-term capital move-

ments, though generally the current account surplus has been insufficient to cover net expenditures on capital and official donation accounts. (2) U.S. products have become less competitive in world (including U.S.) markets, largely because increases in labor productivity have failed to offset money-wage increases. These two points are set out by the contributions from Walther Lederer and R. N. Cooper, Jaroslav Vanek and Egon Sohmen. While the possible contribution to the foreign deficit by U.S. monetary and fiscal policies is dealt with less than it would deserve, Vanek attempts, plausibly but in the nature of the case hypothetically, to trace parts of the deficit to some longer-run developments. The case for the need to increase international liquidity—argued in any case only by two contributors, Roy Harrod and Robert Triffin—is based on qualitative considerations: lack of liquidity prevented a sufficiently strong domestic expansion (Harrod) and led to a dangerous extension of the U.S. role as reserve-currency country (Triffin).

As to policy aims, it is generally agreed that (1) the U.S. balance-of-payments deficit should be reduced, and (2) that the U.S. economy should expand more rapidly and provide more employment than it has recently done, but that domestic credit restraint (not always very precisely specified) is likely to interfere with the achievement of these objectives (only Gottfried Haberler clearly dissenting). It is also fairly generally agreed (3) that there should be no less, and probably more, aid to underdeveloped countries and to countries needing military assistance, though it should not necessarily be provided by the United States.

The policy prescriptions, rather severely limited by the facts and the objectives of the case, are mainly three for the U.S. balance of payments: prevent an increase in money labor cost per unit of output in the United States compared with its competitors (Haberler), devaluation of the dollar (Harrod and Vanek), and transfer of the burden of aid financing from the U.S. to surplus countries in Europe (E. M. Bernstein); and two for the alleged lack of liquidity: raise the price of gold (Harrod) and reorganize the International Monetary Fund so as to abolish reserve currencies and provide more foreign aid (Triffin).

There can be little quarrel about the basic facts. The evidence on decreasing U.S. competitiveness, qualified as it must be by the nature of the relevant statistics, is acceptable enough. However, the presentation of the U.S. balance of payments, made by Lederer on the pattern of the U.S. Department of Commerce and unfortunately not discussed by any of the other contributors, tends to exaggerate the magnitude of the problem.¹ This presentation includes in the balancing item—i.e., in effect in the measure of the U.S. deficit (though not of the surplus), the increase of gross U.S. liquid liabilities not only to official but also to private holders. This has two inconvenient consequences. The U.S. deficit, the diminution of which is the object of policy, includes those increases in liquid foreign dollar claims which are a natural growth of

¹ See on this issue the telling critique of the official U.S. statistics by Walter Gardner ("An Exchange Market Analysis of the U.S. Balance of Payments," International Monetary Fund, *Staff Papers*, May 1961.) This article also gives some calmly reasoned discussion of size and remedies of the deficit problem.

international reserves, considering the annual rate of growth of international transactions (world trade is estimated to have grown by 12 per cent in 1960). So long as the U.S. dollar continues as a reserve currency, this is inevitable. Nor does it threaten international, or U.S., liquidity provided there are no other factors that diminish confidence in the dollar. Secondly, this presentation of the facts does not allow for the fact that, with free convertibility, the threat to the proper functioning of the present international monetary system from foreign holdings of short-term claims on the United States cannot be distinguished from that from domestic holdings of such claims. Why then worry about the one and not about the other?

Thus, either one would have to say that a large part of what is now defined as the U.S. balance-of-payments deficit is not only no cause for worry, but desirable,² or the definition would have to be revised. The difficulty is not purely linguistic, as witness the "crisis" title of the book and the undertone of emergency in many of its passages.³ It could be removed, if one were to distinguish between the balance-of-payments deficit and balance-of-payments weakness, especially in the case of a reserve currency country such as the United States: a deficit to consist of a decline in *gross official* holdings of liquid foreign assets, and a balance of payments said to be the weaker, the larger are *gross* liquid foreign liabilities, but taking into consideration also the role of the country as a reserve currency country, and its rate of domestic monetary expansion. This would put the emphasis where it belongs, i.e., on the balance of payments on current and long-term capital account, on the performance of the United States as a reserve currency country and on its internal monetary (and fiscal) policies. The question of how large the annual growth of liquid U.S. liabilities to official holders should be, is touched upon, interestingly but briefly, only in Vanek's paper (pp. 173-75). The apparent dilemma between reducing the U.S. deficit, presumably desirable, and the reduction of international liquidity with the mopping up of liquid claims on the United States, presumably undesirable, remains unresolved.

There cannot be any quarrel with the proposition that the U.S. economy should grow faster, at lower levels of unemployment. It is not altogether clear, however, what is meant by the point, recurring in many places in the book, that the recent balance-of-payments deficit hamstrings the freedom of policy action designed to reach these objectives. More, it is argued with some force by Harrod that the shackles put on such action by the failure to raise the dollar price of gold are even more noxious. Surely the case for more monetary expansion in a deficit country is no stronger for the United States than for any other deficit country. More precisely, it is strong only where it could be shown that monetary expansion would produce an expansion of output such

² The comparison of the total of all U.S. foreign liquid liabilities with the U.S. gold stock (or even "free" gold) should really not be dignified by as much attention as it gets, even from a very narrow banker's point of view.

³ For instance there is no need to provide gratuitously glaring stage lighting for Triffin's apocalyptic three indictments of the present system—i.e., that its functioning depends on "the hazards of gold digging . . . ; Khrushchev's policies about U.S.S.R. gold sales . . ." and "the perpetuation of our balance of payments deficits . . ." (p. 284).

that exports would rise more than imports. That such cases are possible has been shown by recent experience in several European countries and in Japan; and no matter how one would arrange the details of the analytical treatment of these cases, it would seem clear enough that domestic expansion—or, if you prefer, development—need not endemically produce balance-of-payments deficits. In these cases, initial foreign deficits were no lasting straight jackets; they were financed and disappeared. The problem how to combine expansion of output with growing competitiveness is more than a matter of monetary expansion on the basis of larger international liquidity. The absence in the book of any attempt to exploit this experience (even in Sohmen's contribution on "The Dollar and the Mark") leaves a disturbing undertone of despair leading to the recommendation to devalue the chief "key currency," and a proclivity to gadgets (see Harris' list of 28 remedies, pp. 2-3). It is not fully offset even by Haberler's excellent advice to hold wage advances a little below productivity increases in deficit countries and to push them a little beyond that in surplus countries, because the implementation of such a policy is not fully specified. Neither increasing international liquidity nor devaluation would be sufficient to produce more than temporary relief unless expansion could be assured to be accompanied by increased competitiveness. They are unlikely even to be necessary. The probability is that existing institutional arrangements, especially those centered on the International Monetary Fund, are sufficient to finance the temporary deficits. The remainder of the problem is a matter of domestic flexibility within an over-all disinflationary fiscal and monetary policy.

There is another aspect of the complaint about insufficient international liquidity. It is argued—explicitly by Harrod and implicitly by Triffin—that the lack of international liquidity "has prevented one free country after another from adopting a policy of economic expansion" (p. 46). If this means that these countries have been prevented from expanding beyond the means available to them short of the desired increase in foreign assets, then increasing international liquidity is in effect here recommended as a means of international redistribution of resources (e.g., à la Triffin through replacing key-currency and gross Fund assets by obligations of underdeveloped countries).⁴ Such a redistribution may or may not be thoroughly desirable; in any event it would better allocate responsibility and accountability where they belong, if it were engineered through institutions already existing for the purpose.

The shift of part of the burden of foreign aid from a United States in deficit to European countries in surplus, such as Western Germany, that represents the core of Bernstein's contribution to this book, is debated on two grounds. On one side it is argued that aid is largely tied—in effect or ex-

⁴Triffin makes great play with the odiousness of carrying coal to Newcastle. But a reserve currency country must borrow short and under present international practices, will probably lend long (or donate): the coal is re-exported to where warmth is presumed to be needed. Moreover, as becomes clear from O. L. Altman's Triffin critique, the re-export of the coal through a remodeled Fund carries no guarantee of combining the creation of resources for underdeveloped countries from nowhere with that of a new form of international liquidity that would cost lower risks than the present system.

plicity—to U.S. exports (see e.g., Vanek's paper), and no large balance-of-payments benefit would be produced for the United States by the proposed shift. On the other, it is argued that, if anything, Germany is overexporting, and the United States underexporting, and there is thus no justification for the shift (see Sohmen's paper). But the benefits Bernstein hopes for would occur only if aid financing could be untied from exports and shifted from the United States to say, Germany without changing export origins. In fact, tying aid finance to exports can be justified only if it induces the tying of European exports to European aid financing, thus eliminating untied U.S. financing of European exports to aid destinations (but, it is to be hoped, more than this, i.e., European finance of U.S. aid exports).

Little more needs to be said at this late date about Triffin's proposals. The case for an increase in international liquidity beyond what present institutional arrangements can provide is not established. It is true that the case for substituting a form of international liquidity that does not consist of liquid liabilities of any group of individual countries, and the eventual establishment of a central bank of central banks, is perfectly arguable. However, as Altman has shown, the particular Triffin scheme presented in this book does not free the growth of international liquidity from the risk now involved for the present reserve currency countries; the scheme does nothing in effect to reduce the preoccupation with guaranteeing convertibility of international reserves into gold. The substitution of unconditionally available international liquidity for liquidity conditionally provided, as in the present policy practice of the Fund, would remove the combination of flexibility with discipline that is one of the major advantages of Fund operations. The combination of the scheme with increased development aid is deceptive or unnecessary.

HERBERT K. ZASSENHAUS*

*The author is a member of the staff of the International Monetary Fund. The views expressed here are his own and do not necessarily reflect those of the organization with which he is connected.

Economia internazionale. By GIUSEPPE UGO PAPI. Turin: Unione Tipografico-Editrice Torinese, 1959. Pp. xix, 539. L. 4500.

This very impressive volume on international economics by a distinguished Italian economist is the eighteenth of twenty authoritative books in a cohesive series edited by G. Del Vecchio and C. Arena, of the University of Rome, under the title of "Italian Treatise on Political Economy." (Each of the other nineteen works, written by an outstanding Italian scholar, or scholars, deals with a major field of economics ranging, for example, from principles of economics to economic forecasting.)

At the outset, the author outlines what, in the most widely accepted sense, he considers to be the scope of international economics, namely, an inquiry into: (a) causes of economic development of a country; (b) causes of economic fluctuations (i.e., cycles) within which development takes place; (c) causes of the spread to other countries—through international trade—of the manifestations of development and fluctuations occurring in one country or

group of countries; (d) policies designed to attenuate the size and duration of fluctuations; and (e) policies to promote economic development of a country or region, including present-day processes of regional economic integration.

Topically, the subject matter of the book may be divided into eight parts: (1) a survey of concepts of development in the history of economic doctrine; (2) elements which favor and those which obstruct economic development of a country or region; (3) economic fluctuations and development; (4) influence of employment theories of Keynes and Pigou on business cycle theories; (5) stabilization and anticyclic policies and measures evaluated as to the effectiveness of each; (6) integration of economies as a typical development policy: the European Economic Community as an example; (7) proposal for the establishment of a Free Trade Area; and (8) concerted measures by governments of integrated countries essential for economic progress.

Papi re-examines the classical theory of international trade, or the Ricardian doctrine of comparative costs, and summarizes the main bases on which it has been criticized; namely, (1) that the hypothesis of international immobility of productive factors is invalid; (2) absolute differences in costs as well as comparative differences in costs furnish the basis for international trade; (3) Mill's contribution of the concept of reciprocal demand is inconclusive because the price of a good cannot be stated definitely in terms of another due to the difficulty of determining elasticity of demand for each good a priori; (4) the assumption of bilateral barter underlying classical theory is unrealistic because international trade is in fact multilateral; and (5) Ricardian conclusions are complicated a great deal when comparisons must be made between more than two countries and more than two goods. However, even leaving aside these criticisms, the Ricardian theory remains valid only when there exists a possibility of choice of goods to be produced as a result of a comparison beforehand between the goods that a country can produce or export in payment for goods that it wants to import.

The author then requalifies Ricardo's theory by offering a more general formulation of his own. This consists in the establishment of a ratio not between costs expressed in terms of labor-time, but between supply prices expressed in money terms, which, in each case, simultaneously will enable entrepreneurs to produce a good, and, at the same time, assure its sale in a market or markets. An actual example may be seen in trade between economically integrated countries (The European Economic Community). Here, trade is stimulated by a favorable relationship between supply and market prices that are reduced as a result of internal and external economies arising from integration itself.

Papi has produced a stimulating study in which theory and reality are woven together skillfully and presented in a scholarly style. Because of the lengthy discussion of the European Economic Community and the absence of any extended consideration of backward or underdeveloped countries, the book might be considered to lack balance. This, however, is more than offset by the plethora of original ideas which it contains.

NICHOLAS M. PETRUZZELLI

Silver Spring, Maryland

Free Trade, Protection and Customs Union. By L. H. JANSSEN. Leiden: H. E. Stenfert Kroese, N.V., 1961. Pp. viii, 157. f 20.

This work is an admirable attempt to extend our theoretical and empirical knowledge of international trade with special reference to customs unions. With considerable skill in manipulating algebraic, geometric and numerical techniques the author traces, in respective chapters, trade equilibrium with one scarce factor, two scarce factors, import duties with specialization, and import duties with incomplete specialization, under classical assumptions. The succeeding chapters critically examine Verdoorn's model for customs union analysis, and introduce Janssen's own approach to the subject under conditions of complete and incomplete specialization. The penultimate chapter presents some empirical results for the European Economic Community and the book concludes with a summary and four mathematical appendixes, the first three of which are on elasticity relationships.

Although the technical mathematical knowledge required of the reader is not high the book is not easy reading. To a certain extent this is due to the nature of the subject and the necessity of becoming acquainted with complicated notations, but it is also a matter of the exposition. Instead of listing up to 20 equations and then describing them, for example, the author might preferably, in view of the large number of different models, have followed each equation by its explanation. Also, there is nowhere given a single general system of equations from which the reader can spot particular models as special cases, with the consequence that the reader must work to discover the basic model from which the results are given in those cases where the system is provided only in differential form.

These remarks would bear less force if one could be confident that the results are free of significant error; there are, however, mistakes in logic and interpretation. For example, when Janssen calculates the effect of a tariff on the terms of trade he appropriately divides his model, for expositional purposes, into two phases: the first phase is the excess demand for one of the goods caused by the tariff at constant terms of trade and the second phase is the excess supply of that good due to changes in the terms of trade. This is traditional theory except that the coefficient of the change in the terms of trade, which is usually taken as the sum of the elasticities less unity, contains, in Janssen's result, an income effect arising—even in the complete specialization model—from the "increased value of production" (e.g., p. 36), whereas the income effect is already incorporated into his price elasticity (as Janssen himself points out in Appendix I). The simplest way to prove the error is to see that Janssen would get different results if the terms of trade were allowed to adjust through changes in foreign export prices, an invalid result in a non-monetary model.

A further error arises from the author's attempted proof that the elasticity of demand for imports must be unity or greater, a mistake based on incorrect reasoning about the relation between average and particular income elasticities of demand. Since it cannot be proved that the income elasticity of demand for imports is unity, it cannot, as a consequence, be demonstrated that the price elasticity is unity or greater.

The empirical results from a study of E.E.C. are interesting. The gains from increased specialization are largest for Italy, but only amount to .1 per cent of total production. The specialization effect is indeed swamped in most cases by the welfare effect of changes in the terms of trade which, under one set of assumptions, will raise income in the Netherlands, B.L.E.U., West Germany, France and Italy, respectively, by percentages of 3.00, 3.22, .33, -.28 and -.12. In other words France and Italy (largely because they had high initial tariffs) will lose on balance from the customs union while the other three countries gain slightly. These results are all the more surprising in view of Janssen's calculated increases in exports of West Germany, France and Italy due to the customs union of over \$2 billion each.

The results lead the author to conclude "... the advantage of the customs union *in itself* can scarcely justify, if at all, the painful and by no means easy process of adjustment which it entails" (p. 139). Certainly if these estimates are even reasonably appropriate the conclusion would appear to be justified. Yet the author makes much of a quotation from W. A. Lewis to the effect that "this is an exercise, not a prediction" but nevertheless utilizes his exercise to make a prediction.

On a more philosophical level, there have appeared in recent years studies purporting to demonstrate that the welfare loss due to monopoly is small, that the welfare importance of efficiency and production is exaggerated, and that gains from trade and the welfare gains from tariff reduction are almost negligible. Unless there is a thorough theoretical re-examination of the validity of the tools on which these studies are founded, and especially of the revitalized concepts of producers' and consumers' surplus, some one inevitably will draw the conclusion that economics has ceased to be important!

I should not want to conclude leaving the impression that this work is not a valuable addition to the literature on international trade. It is in fact a necessity acquisition for any economist engaged in the empirical evaluation of the gains from customs unions, and a useful work for the more general economist as well. There are numerous theoretical insights into elasticity relationships (in the appendixes); particularly useful in this connection is his extended treatment of value elasticities and elasticities of substitution in a multicommodity system. His theoretical models of classical theory should make excellent exercises for graduate students especially in view of their combination of geometric, algebraic and numerical techniques. Finally, one cannot but admire heroic attempts to quantify the gains from increased trade on such a high level of generality.

ROBERT A. MUNDELL

International Monetary Fund

An Essay on Trade and Transformation. By STAFFAN BURENSTAM LINDER.
New York: John Wiley & Sons; Stockholm: Almqvist & Wiksell, 1961.
Pp. 167. \$5.00.

This book by a young Swedish economist deals with two old and fundamental questions of international trade. One is the gains from trade, and the

other is the basis for trade. On both he has important things to say, and especially on the latter, some novel ones.

A country's gain from trade rests on both a consumption and a production effect. The latter, in turn, requires an internal transfer of factors. If factors can not be absorbed in an alternative sector after being displaced, the production effect must be negative. Depending on whether or not the consumption effect is stronger than the production effect, the effect of expanding trade on a country's welfare can be either positive or negative. Downward flexibility of factor prices, however, would permit continued employment of factors in the import-competing sector and leave the country with at least the consumption gain.

Here we meet Linder's u-country, in which there is lack of transferability, and the wage is at subsistence level. Real wages do fall in the import-competing sectors, where they lead to a population decline. In the exporting sector there is a rise of per capita income and population. The growing exporting sector produces an ever-greater share of the national product and ultimately there would be a gain of per capita income; but this adjustment might be a very long and painful one. And once committed to a high degree of specialization, such a country might be caught in periodic terms-of-trade squeezes, such as have beset the primary exporters.

Contrasted with the u-countries are the growth countries, which differ in being able to reallocate both consumption and resources instantaneously. The gain from trade increases the growth base which is compounded to give a new higher growth path. Here he distinguishes between gains from one-time reallocation and those from current allocation which increase the growth rate (p. 65). The latter he regards as especially important for such countries as Australia, Canada, New Zealand. Their rate of growth was augmented by the flow of technical contacts and information, the stimulus to entrepreneurship, the inflow of foreign capital, and possibly by the reduction of internal market distortions through international competition. Cited with approval in this connection are such writers as Haberler, Nurkse, Ohlin. He contrasts with this the infant-industry case for protection, which admits that the growth *base* because of adverse allocation might initially be smaller under protection, but claims that the growth *rate* would be higher than under free trade.

Linder puts forward an important new thesis on the basis for trade. Trade in primary products is correctly explained by differences in factor endowments. Trade in manufactures, on the other hand, is explained not mainly by differences in factors, but by similarity of demand patterns in the trading countries. Industries develop in a country because of the existence of potential home markets. An entrepreneur is more likely to gauge accurately a need on the domestic market, which is relatively familiar to him, than one abroad. New inventions available for exploitation will similarly be geared to some domestic need. Only when the home market has permitted the industry to attain a sufficiently large scale of operations does it become competitive on world markets. A developed industry in one country generally operates on an entirely different production function from an embryonic industry in another country. The strongest foreign market is then found in countries where per

capita income is at the same level and the composition of demand is about the same. It is, however, fairly easy for the direction of trade in particular manufactures to change, because a number of countries with similar income levels also have similar industrial structures.

The proposition above is subjected to a test given in two forms. This is to compare the import propensities between similar-income countries with those for dissimilar countries. In a tabular form of the test, countries are arrayed vertically and horizontally (top to bottom and left to right) in order of per capita incomes. If the thesis is valid there should be a tendency toward bunching of the high bilateral import propensities around the main diagonal. While there is no test of goodness of fit, inspection suggests that high propensities are in fact found between countries with similar per capita incomes. Scatter diagrams for individual countries, with import-propensities and per capita incomes on the two axes, suggest the same conclusion.

Linder is well aware of the forces tending to distort such a relation: cultural and political affinities and tariff preferences on the positive side; narrowness of geographic horizon and high transport costs on the negative side. But in the reviewer's opinion he has given us an important supplemental explanation for trade in the modern world.

Where does this leave the law of comparative advantage? For primary products resource endowments are undisputedly the basis for specialization and trade. For manufactures their role becomes distinctly smaller. In my view Linder's case is strengthened by the impact of modern technology. A century ago manufacturing activity was tied down to local supplies of raw material and fuel much more than today. Development of synthetics on the one hand and rapid advances in transportation on the other have weakened the old connections and made the geographic pattern of industry more flexible.

The foregoing proposition clearly does some damage to the factor-price equalization theorem. The main means for developing a favorable export position in some product is to have a strong home demand. This permits the industry to reach competitive size and develop an advanced technology. Relative factor abundances are not very important, says Linder, compared to size of home market and level of technology. If it's not necessarily the factor-abundant industry which expands, there's no reason to expect trade to make abundant factors scarcer.

In my view this pushes the argument a bit too far. Let us take the advanced countries together, including the top twenty-one in his list. The variation in per capita income from the United States to Japan is in a ratio of twenty to one. These two countries and most of those between have comparable education, health, and technology. There is a strong overlap in their industrial structures. An expansion of Japanese industries at the expense of agriculture appears to be taking place today at rising opportunity cost—labor has grown very scarce, and wages are rising, along with a growth in foreign trade. And with the growth of trade goes a further evening out of technology. It is hard to believe that her lower wages would not favor her relatively labor-intensive industries and in turn raise the wage level.

A final point deals with the relation of a country's economic size to its im-

port propensity. The hypothesis is that the larger is a country's total income, the more trading it does with itself internally, and the less it does relatively with the outside world. He tests this hypothesis graphically and finds that such a relation exists. But there is apparently no relation between per capita income and trading intensity; that is, countries with higher per capita income do not have higher import propensities.

This modest-sized book is a real contribution. Linder's main ideas give little to quarrel with; this reviewer differs only with his degree of de-emphasis of factor endowments, and along with it, his negation of the factor-price theorem.

FRANZ GEHRELS

Indiana University

Industrial Materials in Canadian American Relations. By BERNARD GOODMAN. Detroit: Wayne State University Press, 1961. Pp. xvii, 217. \$7.00.

This book is best described as a synthesis and extension of the commodity analysis and forecasts of the Paley Commission in the United States and the Gordon Commission (Royal Commission on Canada's Economic Prospects) in Canada. The scope is limited to those industrial materials which are imported into the United States from Canada. The main concern is with long-run forecasts of this trade. It is a useful little book because it pulls together commodity analyses from many sources. It is not a sophisticated study; no use is made of input-output techniques, nor of econometric models. Regarding items of which this reviewer has some knowledge, the forecasts appear to be reasonable. The book is quite well written and it is well-indexed.

Canadian exports of industrial materials to the United States are mainly forest and mineral products. After an initial sketch of the trade, each of the main items is considered separately, including lumber, pulp wood, woodpulp, newsprint, nickel, copper, aluminum, lead, zinc, iron ore, uranium, petroleum, natural gas, asbestos, titanium, platinum and gypsum. A standard procedure is followed in the analysis of each item. The past and current experiences are reviewed and then forecasts are developed. In each case, United States consumption, production, and total imports of a material are reviewed and forecast. From these estimates and from forecasts of United States imports from non-Canadian sources, derived demands for imports from Canada are obtained. The Canadian supply conditions are set out and related to these derived demands. Then, for each commodity some effort is made to check on the consistency of the elements in the forecast.

To an incredible degree forecasters are "prisoners of their times." For example, Goodman's forecasts for Canadian exports of forest products to the United States are less optimistic than were those of the Gordon Commission. In 1955 and 1956 when the latter group was at work the improving competitive prospects of United States newsprint production were still discounted heavily in Canada. By 1960, when Goodman wrote his book, the relative weakening of Canada's export prospects to the United States in forest products was more accurately assessed. Or was it? The same point arises regarding Goodman's scaling down of earlier forecasts of Canadian exports of alumi-

num to the United States. More generally Goodman's book reflects some of the doubts about the favorableness of Canadian long-term economic prospects which developed after 1957.

Goodman begs off from discussing most of the big issues of industrial materials in trade and economic development, even of Canadian-American economic development. This is fair enough. But there are some matters which he might reasonably have been expected to consider (and does not) within the scope of his study. First, he might have aggregated the forecasts of trade in the various items and examined the aggregates in relationship to the prospective size of Canadian national output and the over-all trading position. There is no way of being sure that the bits and pieces are consistent with one another unless some such procedure is applied. Moreover, nations are at least as much interested in their over-all economic position as in particular segments of the situation. Secondly, a particular long-term economic forecast of a twenty or twenty-five year trend cannot hope to provide a reasonably accurate view of prospects for a decade ahead. This is not an argument for abandoning twenty or twenty-five year forecasts. Rather, it is a plea for attention to "long cycles" in long-range forecasting work. The Gordon Commission forecasts (1956 and 1957) have thus far (1962) been misleading guides to Canada's experience. Goodman makes no systematic effort to work long cycles into his analysis.

Systèmes fiscaux et Marché Commun. By L. REBOUD. *Récherches Économiques*, Vol. 6. Paris: Sirey, 1961. Pp. v, 374. NF 24.

With the rapid progress of the European Economic Community (EEC) Mr. Reboud's book on the fiscal systems within this community comes at the right time.

Large problems and many difficulties will of course still have to be overcome before the Common Market area as the Treaty of Rome envisages it will be a reality. Reboud treats one of these: the problem of differences in fiscal systems. The book limits itself to one particular aspect of the fiscal systems, namely taxation. Expenditure policies and national debt problems are not investigated.

The author analyzes possible "distortions" which may arise within the EEC as a result of differences in taxation. By "distortions" the author has in mind influences which will interfere with the working of a competitive free market system and the flow of capital within the EEC area.

He distinguishes three kinds of distortions, those of a short-, medium-, and long-run nature. Although short-run taxation-induced distortions could be overcome through adjustments in exchange rates, these have much too general an effect and cannot take account of different tax burdens imposed on commodities. With fixed exchange rates, adjustments are too cumbersome to eliminate slight price discrepancies due to taxation. Flexible exchange rates,

if they should be reintroduced—which is unlikely—would have the same disadvantage and create in addition the possibility of distortions through speculation. The author dismisses, therefore, exchange-rate adjustment as a corrective force for differences in taxation, except for those cases where discrepancies are extremely large.

A second possible way of equalizing differences in taxation in the short run is to impose offsetting taxes on imports, as is actually done now. The difficulty with this method is that it is not certain what part of taxes contained in the price of the imported good is actually compensated. If, for instance, France exports a commodity to West Germany, the French will sell it free of sales taxes but the West Germans will impose their equalizing *Umsatzsteuern*. Other French taxes which are contained in the price, like income and property taxes, if shifted and recovered in price, cannot be accounted for. Therefore, the imposition of such equalizing taxes to compensate differences in tax burden is a crude and imperfect method. In many cases, they may actually be disguised protective tariffs. The author concludes, however, that in the short run, a "harmonization of taxes" through exchange rate adjustments for general and large differences and a system of equalizing taxes for selective use will be sufficient. The use of *Ausgleichsteuern* would, however, require the maintenance of controls over exports and imports which is one of the things the EEC is supposed to abolish. These methods provide, therefore, at best, a temporary solution only and must eventually be superseded by a better and more complete integration of the fiscal systems.

Reboud believes that the second stage of fiscal integration will require a coordination of fiscal policies. A policy of promoting price stability and full employment would be desirable. The author tries to assess the contributions the various tax systems could make to such a stabilization policy. To what extent such policies may necessitate an interference with the allocation of resources through a free market mechanism, which is throughout the book the guiding criterion, is unfortunately not brought into sharp focus. In the author's discussion of many of the topics in this context much more quantitative information than is actually available about EEC fiscal systems would have been necessary. Often he has to make bold guesses, and some of these are inevitably very speculative. When, for instance, the total incidence of the EEC tax systems is discussed, his statement that the progressiveness of these systems is about the same must surely be questioned. Very little is actually known about this.

The last section of the book deals with long-run implications of differences in taxation. The focus here is on capital formation in the private sector. The author devotes quite a few pages to the differential effects of the various inheritance taxes, and many readers will probably feel that he greatly overestimates the importance of these for capital formation. A discussion of the effect of income taxes on investment follows closely that in standard literature. The conclusion is that under the existing systems of taxation, long-run distortions in the structure of production in the EEC are inevitable because capital formation is favored differently in the private sectors. Capital formation by gov-

ernment—certainly large in France as well as in West Germany—as an important ingredient for the effective working of the future EEC is not investigated.

The merits of the book are that it informs the reader about existing differences in taxation in the EEC countries. It sets forth the legal provisions and discusses at length the economic effects of the various taxes as is done in better standard textbooks on taxation. There are interesting details about taxation in France, West Germany, and Italy. The subjects discussed range from the pyramiding of turnover taxes to loss offsets as factors influencing investment decisions. Most of the book is in fact a treatise on taxation, made interesting through international comparisons. This has the unfortunate effect that the central topic, namely what will happen to the EEC if these differences in taxation continue to exist, often gets only somewhat casual treatment.

One cannot help feeling that the author overestimates the danger of possible distortions through differences in taxation for the EEC. In the United States, differences in taxation in the various states do not seem to have caused too great disturbances. Variations in other cost items like transport, energy, and labor are evidently much more important for competitiveness than taxes. The situation will probably not be much different in the EEC.

There are no doubt some important discrepancies in taxation which should be eliminated. Adjustments will have to be made in turnover taxes and selective excises and one of the first victims may be the West German *Umsatzsteuer*. For other taxes this does not seem to be so urgent because they often have a similar effective incidence and create a comparable burden or have insignificant yields. As the EEC tax systems are the outcome of long historical developments and reflect different social, economic, and psychological attitudes, this reviewer can only agree with the author that for a complete fiscal integration of the EEC countries changes should be made, but they should be made slowly.

Corporate Debt Capacity: A Study of Corporate Debt Policy and the Determination of Corporate Debt Capacity. By GORDON DONALDSON. Boston: Graduate School of Business Administration, Harvard University, 1961. Pp. xiv, 294. \$4.00.

Studies of corporate debt structure, financial risk, and capital cost have taken such divergent directions in recent years that an unfortunate gulf has developed between the empirical case approach and that of abstract mathematical theory. Donaldson's monograph goes a long way toward bridging this gap by utilizing system and orderliness in his case studies, realism and common sense in his theorizing.

The book is a veritable model of a research report. The first of the two parts is an account of a conventional funds-source and use analysis and of an inquiry into the policies which corporate officers follow (or think they follow) in managing their debt; the second is an analysis of their actual practices and

a demonstration of an ingenious method by which they might avoid a good deal of the arbitrariness inherent in generally accepted principles of borrowing.

Twenty companies constituted the universe of the investigation, four established firms in each of five industries: machine tools, baking, chemicals, ethical drugs, and rubber. It is clear that much careful and objective thought went into the selection of the sample, providing an ample base for generalization about a broad segment of U.S. industry. (Certain important areas were not represented in the sample—regulated industries, for instance, and financial firms—and so did not figure in the conclusions.) The research began with a study of the funds flows through the twenty firms during the period 1939-58, with emphasis on sources, internal as well as external. Interviews with the financial officers of the selected firms about their attitudes toward debt capacity brought out that their approach was somewhat stereotyped and not very deeply analytical. They cited several borrowing-policy standards, such as borrowing the maximum available at the prime rate, borrowing the maximum consistent with an A credit rating, limiting the long-term debt to some widely recognized per cent of total capitalization, or holding to some generally accepted earnings coverage of interest; but their standards manifested primary reliance on the judgment of others, especially creditors, and very little independent evaluation of their own.

Donaldson's own thinking about the effect of debt upon financial risk leads him to the conviction that of the various common approaches to debt standards the most useful lies in coverage analysis—not, however, in terms of earnings, but in terms of cash flow. In order to provide a rigorous demonstration of this approach he develops a system of equations—mathematical but not elaborate—which take into account the principal determinants of cash flow. Postulating that management will be able from past experience to provide quantitative values for these determinants reflecting their probable behavior in recession, he thus offers a means of evaluating the risk that cash flow may descend to the region of *cash inadequacy* and, in the extreme, to the point of *cash insolvency*. Debt service is treated as only one of the several factors. "The recession cash flow analysis is therefore seen to be a necessary preliminary to a whole set of financial decisions involving fixed cash outflows, and the opportunity for long-term debt financing clearly cannot be decided independently of other purposes to which a willingness to bear increased risk might be put" (p. 215).

Application of his method to five of the companies—one from each industry—leads him to conclude that the conventional types of debt capacity standards are outmoded and that balance-sheet and income-statement ratios are inadequate as guides to decisions on debt policy. He concludes, further, that if financial officers would use the cash-flow approach they might see more clearly that debt policy is only one of the factors bearing on the financial risk and thus reach their decisions less arbitrarily and more rationally. The argument and the evidence are both persuasive.

Competition in the Aluminum Industry: 1945-1958. By MERTON J. PECK.
Cambridge: Harvard University Press, 1961. Pp. vi, 227. \$5.25.

Until recently, most beginning students in economics first learned about monopoly by being introduced to the Aluminum Corporation of America. As Professor Peck's study makes clear, the time has come for economists to find another "real-life" example of the sole producer to serve their pedagogical purpose. Indeed, the aluminum industry has now so far degenerated toward workable competition that it is no longer a very good example of oligopoly.

The steps by which Alcoa's complete control of aluminum reduction capacity in 1939 gave way to a one-third share in 1958 are succinctly described. Since the courts resolutely refused to order dissolution or divestiture, the decline of Alcoa is traceable to legislation and what may be a new form of antitrust—"regulation through public opinion, the vague consequences of Congressional displeasure, and the policies of miscellaneous executive agencies" (p. 1). That competition—given any reasonable definition of the term—has increased in the aluminum industry over the last twenty years is clear enough. The interesting question is how much (if anything) the economy paid in lowered efficiency to secure this increase in competition. Peck declines to consider this issue directly, possibly because the evidence does not permit an answer in which one can have much confidence.

Each new entrant to the industry since 1939 has owed its start to the bounty of government agencies during the Second World War or the Korean conflict. Yet the jibe often made that competition in aluminum is the result of artificial insemination is misleading. The major rivals created for Alcoa by government favor—Reynolds and Kaiser—were, of course, chosen instruments of federal policy. But then in a war mobilization, every firm that is conscripted or created is a chosen instrument. Did the government choose wisely? Though Peck does not say it, his results permit the inference that we would have had cheaper aluminum during the Second World War had the expansion of aluminum capacity been entrusted to the old experienced monopolist. Likewise, if the efficient production of aluminum ingot had been the only goal, the surplus government plants should have gone to Alcoa after 1945. In defence of federal policy, it can be said that the learning period for a new ingot producer is not long; and that by the early 1950's, Reynolds and Kaiser were able to take care of themselves in a free market. "In 1949, Alcoa not only was considerably larger than Reynolds and Kaiser, but it had approximately a 10 per cent cost advantage and considerably greater financial resources. But, just as the relative size of Alcoa is now nearer the other two, Alcoa's cost and financial advantages have also declined" (p. 18).

Peck apparently accepts the view that the government decision to break Alcoa's monopoly on ingot production was a good thing. (A plain statement of the author's personal preference seldom intrudes in this book.) He has, however, no enthusiasm for proposals that would use federal power to force a further increase in the number of firms. His reading of the evidence indi-

a demonstration of an ingenious method by which they might avoid a good deal of the arbitrariness inherent in generally accepted principles of borrowing.

Twenty companies constituted the universe of the investigation, four established firms in each of five industries: machine tools, baking, chemicals, ethical drugs, and rubber. It is clear that much careful and objective thought went into the selection of the sample, providing an ample base for generalization about a broad segment of U.S. industry. (Certain important areas were not represented in the sample—regulated industries, for instance, and financial firms—and so did not figure in the conclusions.) The research began with a study of the funds flows through the twenty firms during the period 1939-58, with emphasis on sources, internal as well as external. Interviews with the financial officers of the selected firms about their attitudes toward debt capacity brought out that their approach was somewhat stereotyped and not very deeply analytical. They cited several borrowing-policy standards, such as borrowing the maximum available at the prime rate, borrowing the maximum consistent with an A credit rating, limiting the long-term debt to some widely recognized per cent of total capitalization, or holding to some generally accepted earnings coverage of interest; but their standards manifested primary reliance on the judgment of others, especially creditors, and very little independent evaluation of their own.
